## Abstract

Seasonal changes in plant leaf area have a substantial impact on global climate. If and when leaves are present affects surface roughness and albedo, and the gas exchange occurring between leaves and the atmosphere affects carbon dioxide concentrations and global water system. Thus, correct predictions of plant phenological processes are important for understanding the present and future states of the Earth system. Here we compare plant phenology as estimated in the Community Land Model (CLM) to that derived from satellites in drought deciduous regions of the world. We reveal a subtle but important issue in the CLM: anomalous green-up during the dry season in many semi-arid parts of the world owing to rapid upwards water movement from wet to dry soil layers. We develop and implement a solution for this problem by introducing an additional criterion of minimum cumulative rainfall to the leaf-out trigger in the drought deciduous algorithm. We discuss some of the broader ecological impacts of this change and highlight some of the further steps that need to be taken to fully incorporate this change into the CLM framework.

## 1 Introduction

Ecosystems change with the seasons in response to environmental cues. Some of those cues are fixed, like day length, while others are climate-driven and therefore vary from year to year. The combination of fixed and climate-driven phenological cues poses an interesting problem in the face of climate change – climate related drivers of phenology (temperature and rainfall patterns) are likely to change (Lau et al., 2013), while fixed cues will remain unchanged. Phenological shifts due to climate change have already been identified (e.g. Parmesan and Yohe, 2003). “Phenology” can refer to a large number of patterns and behaviors in plants and animals that shift with the seasons. Here, however, because we are focused on land surface model simulations, we use phenology specifically to refer to intraannual variation in leaf area index (LAI).

Interactive Discussion

Leaf area can vary significantly within a year and is, therefore, a critical control on land–atmosphere feedbacks (Lawrence et al., 2012).

Recent advances have greatly improved our ability to predict seasonal patterns in northern temperate deciduous forests (Richardson et al., 2012), but our understanding of phenological patterns in stress or drought deciduous plants (also called “raingreen”) remains weak (Guan et al., 2014; Jenerette et al., 2010; Ma et al., 2013). The semi-arid ecosystems that host the majority of drought deciduous woody plants have relatively low biomass but make up a large fraction of global land area (~ 30 %; Scholes and Hall, 1996). Their extensiveness alone makes them important to global radiation budgets, but additionally these systems are likely very sensitive to climate change given their apparent bistability (Scholes and Hall, 1996; Staver et al., 2011). In semi-arid ecosystems leaf-out is typically thought to be a function of water availability (Reich, 1995; White et al., 1997), however, some woody plants do leaf-out several weeks before the first rains of the season (Archibald and Scholes, 2007).

In an Earth system modeling context, the timing and magnitude of plant phenology, and how these processes may change, is critical for approximating the energy and carbon balances of the planet. Prognostic phenology has only recently been incorporated in to earth system models, however, and its fidelity, particularly in semi-arid regions, remains poorly tested (Blyth et al., 2011; Lawrence et al., 2011; Randerson et al., 2009). Lawrence et al. (2012) found that the prognostic phenology in the Community Land Model version 4 (CLM4(CN)) degraded estimates of latent heat flux and other biophysical properties in comparison to using prescribed, satellite-derived phenology (CLM4SP). Wang et al. (2013) compared intraannual variation in the fraction of absorbed photosynthetically active radiation (fAPAR) in CLM4CN to satellite-derived estimates and found substantial differences in regional averages, zonal means, and interannual trends. It is difficult, however, to isolate the impact of the drought deciduous phenology algorithm using these regional and zonal estimates.

Satellite-derived estimates of greenness, the fraction of absorbed photosynthetically active radiation (FAPAR), and LAI have greatly improved our ability to study the en-

5 environmental drivers of phenology (Reed et al., 2009), however, the majority of studies have focused on northern deciduous and boreal forests (e.g. Delbart et al., 2006; White et al., 2009; Yang et al., 2012). While fewer studies have focused on remote sensing of phenology in semi-arid systems, Zhang et al. (2005) found a strong relationship between greenness onset and the start of the rainy season across the semi-arid parts of Africa. They found a weaker relationship, however, between dormancy and the end of rainy seasons, and they attribute this weakness to differences in soil properties. Similarly, Ma et al. (2013) found a strong relationship between greenness and rainfall in northern Australia in both seasonal timing and amplitude and Bradley et al. (2011) found a close relationship between rainfall and seasonality in Amazonian savannas. Interestingly, in Africa Zhang et al. (2005) also showed a strong relationship between latitude and both green-up and dormancy onset, even in the narrow band of the Sahelian and Sub-Saharan region, suggesting a possible link between phenology and subtle changes in photoperiod at least in northern Africa. Recently Guan et al. (2014) showed a relationship between woody plant cover and phenological timing in African savannas.

10 In this study we address three questions related to the representation of drought deciduous phenology in the CLM. (1) How well does the CLM capture phenological patterns of LAI among different drought deciduous plant functional types (PFTs) as compared to satellite-derived estimates? (2) Which parameters in the current version of the CLM have the most leverage on woody plant phenology? And (3) do changes in the phenology algorithms in the CLM improve the model's representation of seasonal cycles regionally?

## 2 Methods

### 2.1 Model description

The CLM is the terrestrial component of the Community Earth System Model (CESM; Lawrence et al., 2011); it simulates biogeophysical and biogeochemical processes including radiation interactions with vegetation and soil, heat transfer in soil and snow, hydrology, and plant photosynthesis and respiration. In this paper we use the most recent release of the Community Land Model, CLM4.5BGC (Oleson and Lawrence, 2013). Henceforth, references in this paper to the “CLM” will refer to CLM4.5BGC.

The CLM is run here on a  $1.25^\circ \times 0.9375^\circ$  grid, and each gridcell is, where applicable, divided into fractions representing vegetated land, lakes, glaciers, and urban areas. Within the vegetated fraction of a gridcell there may be multiple PFTs representing a coarse division of biodiversity along its major axes of variation: trees/shrubs/grass, broadleaf/needleleaf,  $C_3 / C_4$  photosynthesis mechanisms and phenological habit (evergreen, cold deciduous and stress/drought deciduous). There are currently 15 non-crop PFTs in the CLM, four of which follow the drought deciduous phenology algorithm (Oleson and Lawrence, 2013). Figure 1 shows where these different PFTs dominate the globe. Over time the relative cover of the PFTs may shift, as may the overall fraction of vegetation, depending on shifts in land use, though these shifts are minor in recent decades. In the simulations used in this paper these shifts in PFT fractions and cover are prescribed from satellite observations (Lawrence and Chase, 2007) as opposed to emerging from vegetation competition (Bonan et al., 2003).

In the CLM, drought deciduous plants are represented by the “stress deciduous” phenology type, as distinct from the evergreen or “seasonal” (cold) deciduous phenology types. This designation allows for plants to lose their leaves either via the impact of cold, via the impact of drought, or via the onset of short days thus allowing the model to simulate, for example, grass vegetation growing in an environment that is both seasonally cold and seasonally dry. If the triggers for offset are not reached in a given year, drought deciduous vegetation will follow the evergreen phenology algorithm, gaining

and losing fixed fractions of carbon with each time step. This stress deciduous algorithm, described in more detail below and in Oleson and Lawrence (2013), was developed in part from White et al. (1997), though that study was particularly focused on grass phenology.

The deciduous algorithms are hierarchical, such that plants classified as “stress deciduous” but growing at high latitudes or in cold climates will follow the same onset/offset rules as cold/seasonally deciduous plants. From the beginning of a dormant period a “freezing day accumulator” is activated whereby time steps with a temperature below freezing ( $0^{\circ}\text{C}$ ) are summed and if this sum exceeds 15 days then the plants will follow both the winter deciduous and drought deciduous algorithms. Leaf onset can only be triggered if day length is greater than 6 h, a latitude-specific sum of growing degree days has been reached (described in Oleson and Lawrence, 2013) and the soil wetness criteria described below have been met.

In seasonally dry, warm regions (the focus of this paper) where day length is never less than 6 h, leaf onset for the stress deciduous phenology type is determined by soil wetness. At the end of the previous offset period an accumulated soil water index (SWI) is set to zero and accumulation is calculated as:

$$\text{SWI}^n = \begin{cases} \text{SWI}^{n-1} + f_{\text{day}} & \text{for } \psi_{\text{soil } 3} \geq \psi_{\text{offset}} \\ \text{SWI}^{n-1} & \text{for } \psi_{\text{soil } 3} < \psi_{\text{onset}} \end{cases} \quad (1)$$

Where  $n$  and  $n - 1$  refer to the values in the previous and current time steps,  $\psi_{\text{soil } 3}$  is the soil water potential (MPa) in the third soil layer (6.23–9.06 cm),  $\psi_{\text{onset}}$  is  $-2$  MPa, and  $f_{\text{day}}$  is a time step (30 min in CLM) as a fraction of a day. Onset is triggered when SWI exceeds 15 days.

The rate of leaf onset (fraction of onset per time step), which in the CLM is represented as the transfer of C and N from a storage pool to the “display” leaf pool, is determined by the number of days prescribed for onset, here fixed at 30 days. The rate

Interactive Discussion

$(r_{\text{onset}})$  at each time step is defined as:

$$r_{\text{onset}} = \begin{cases} \frac{2}{t_{\text{onset}}} & \text{for } t_{\text{onset}} \neq \Delta t \\ \frac{1}{\Delta t} & \text{for } t_{\text{onset}} = \Delta t \end{cases} \quad (2)$$

where  $t_{\text{onset}}$  is time remaining in the current onset period in seconds and  $\Delta t$  is the length of a time step (108 000 s). The flux of C out of the storage pool is then defined as the amount in the C storage pool at that time step multiplied by  $r_{\text{onset}}$ . These functions result in a linearly decreasing flux out of the transfer pool, so the rate of increase in LAI over the onset period steadily decreases as C moves from the storage pool to the display pool (see Fig. 14.1 in Oleson and Lawrence, 2013). During the onset period C and N are also transferred from storage pools for fine roots, live and dead stem, and live and dead coarse roots into these components respective displayed growth pools. During the growing season, C and N taken up by the plant are accumulated in transfer pools, to be used in the next growing season.

As long as the leaf onset period is complete, leaf offset can be triggered by short (< 6 h) day length, a period of cold temperatures has been reached (described in Oleson and Lawrence, 2013) or if the soil dryness criteria described below has been met.

The offset soil wetness index (OSWI) can potentially start accumulating time steps once the previous leaf onset phase is complete. The algorithm differs slightly from the onset trigger, in that OSWI can increase or decrease as described below.

$$\text{OSWI}^n = \begin{cases} \text{OSWI}^{n-1} + f_{\text{day}} & \text{for } \psi_{\text{soil } 3} \leq \psi_{\text{offset}} \\ \max(\text{OSWI}^{n-1} - f_{\text{day}}, 0) & \text{for } \psi_{\text{soil } 3} > \psi_{\text{offset}} \end{cases} \quad (3)$$

where  $\psi_{\text{offset}}$  is  $-2$  MPa, and leaf offset is triggered when OSWI equals 15 days.

Similar to the rate of leaf onset, leaf offset rate is a function of the amount of time left in the offset period, here fixed at 15 days:

$$r_{\text{offset}} = \frac{2\Delta t}{t_{\text{offset}}^2} \quad (4)$$

Carbon fluxes into the litter pool are only calculated for leaves and fine roots (stems and coarse roots cannot shrink). Nitrogen fluxes into the litter pool reflect retranslocation of N prior to offset. See Oleson and Lawrence (2013) for more details.

The model runs used in the global simulations described here ran for 45 years, and were started from an equilibrium baseline state generated by a standard CLM4.5BGC spin up run, as documented in (Oleson and Lawrence, 2013) and using CRU-NCEP meteorological reanalysis data (N. Vivoy, personal communication, 2011; description available at: <http://dods.extra.cea.fr/data/p529viov/cruncep/readme.htm>; data available at: [http://dods.extra.cea.fr/store/p529viov/cruncep/V4\\_1901\\_2011/](http://dods.extra.cea.fr/store/p529viov/cruncep/V4_1901_2011/)) to drive the model.

## 2.2 Satellite derived LAI

We compared the model-derived estimates of LAI to those estimated from the Advanced Very High Resolution Radiometer sensors (AVHRR) onboard the National Oceanic and Atmospheric Administration satellites. These data are available bimonthly and span from 1981 to 2011. They are supplied at  $1/12^\circ$  resolution. A detailed description of the development of the LAI product (hereafter LAI3g) is in Zhu et al. (2013).

To ensure the most appropriate comparison possible, the LAI3g dataset was rescaled to match the mean monthly LAI output from the CLM. First, the two LAI3g maps generated for each month were averaged, then the LAI3g pixels within a CLM gridcell were averaged. If more than 80% of the gridcell did not have values in LAI3g (mostly applicable at high latitudes), the entire gridcell was removed from further analysis. Finally, the resized LAI3g data was resampled using a nearest neighbor approach to align with the CLM grid. All spatial and statistical analyses were performed in R (R Core Team, 2013) using the *ncdf* (Pierce, 2011), *raster* (Hijmans and van Etten, 2013) and *rgdal* (Bivand et al., 2013) packages.

## 2.3 Comparing LAI3g to CLM LAI

We first compared LAI3g to the CLM output for 1982 (the first full year of LAI3g) to 2010 (the last available year of the CRU-NCEP forcing dataset for CLM), aggregating values by zones based on dominant PFT and hemisphere. To aggregate into PFT classes, we only considered gridcells dominated by a single drought deciduous PFT (> 50% cover), permitting six possible comparisons with a sufficient number of gridcells for comparison: Northern Hemisphere (NH) temperate C<sub>3</sub> grasses ( $n = 180$ ), NH C<sub>4</sub> grasses ( $n = 234$ ), tropical deciduous trees ( $n = 242$ ), Southern Hemisphere (SH) deciduous shrubs ( $n = 68$ ), SH C<sub>3</sub> grasses ( $n = 160$ ), and SH C<sub>4</sub> grasses ( $n = 271$ ). Note that the actual number of gridcells compared from year to year varied slightly with changes in land cover and, in the case of LAI3g, available data. The counts listed here are the averages for each PFT. To visually assess the comparison between LAI3g and CLM we plotted the monthly means and SD for these seven regions. We also computed the  $R^2$  and root mean squared error (RMSE) across all 29 years' monthly values to assess CLM's ability to fit the seasonality and the magnitude of the LAI3g values. Due to the temporal coarseness of these data and the irregular seasonal patterns found in many of our areas of interest, we did not fit a continuous function to these data.

## 2.4 Point simulations and parameter sensitivity tests

Given the observed mismatches between LAI3g seasonality and CLM predictions among drought deciduous woody plants (see Discussion), we conducted an analysis of how the parameters determining phenology in the model affect the model outcome. The use of global or regional simulations to assess the sensitivity of models to their structural and parametric assumptions is problematic on account of both the computational requirements to do so and the high-dimensionality of the model outputs, which can hinder understanding. To avoid these issues, we conducted a sensitivity test to the major model parameters that control seasonality in LAI at the point scale. In these point simulations we focused on low-latitude drought-deciduous ecosystems, and selected

six locations dominated by tropical deciduous trees, grasses, or a combination of the two (Table 1).

The phenology model contains three empirical parameters that collectively describe the leaf onset and offset algorithms.

1. Critical soil water potential ( $\psi_{\text{onset/offset}}$ ) values for leaf onset and offset (default =  $-2$  MPa)
2. Soil water potential days to onset/offset (SWI/OSWI) threshold (default = 15 days)
3. Quantity of carbon assimilation which is directed to current leaf growth rather than storage ( $F_{\text{current}}$ ) (default = 0.0)

To determine what impact the choice of these parameters has on the model outcome, we conducted a Latin-hypercube analysis (McKay et al., 1979), beginning the model from a spun-up state with default parameters. We then perturbed the parameters and ran the model forwards until a new LAI equilibrium condition was detected. The Latin hypercube methodology is a particularly efficient means of investigating a multi-dimensional parameter space, because each run of the model perturbs every parameter, and the algorithm ensures that the distribution of sampled points is distributed efficiently (but not uniformly) through parameter space.

Because the nitrogen cycle is active in CLM, soil biogeochemical equilibrium can in some circumstances (particularly at high latitudes) take many decades or even centuries to achieve, therefore we set a threshold for the new equilibrium state as the absence of a trend in LAI resulting in a 2% increase over a five year period. Given the high temperature and relatively low biomass and productivity of the ecosystems in question, in our simulations LAI equilibrium was in practice typically reached after the first 5 year period of the simulation. As with the global simulations, we used the CRU-NCEP reanalysis forcing data, extracted at the six points of interest, to drive the point simulations.

For this study, since we were comparing the model output to monthly satellite observations, we did not manipulate the number of days for onset (30) or offset (15) to

## 2.6 Global simulations

We used a number of different metrics to globally compare CLM4.5BGC to the LAI3g data and, later, to the modified version of the model (CLM-MOD). First we compared maps of maximum annual LAI and differences between the three maps. We also developed an algorithm to count the number of LAI peaks per year in all three data sets on gridcells with a range greater than one, by counting the number of times per year that the difference between one month's LAI and the next was negative, then taking the mode across all 29 years. Finally, we calculated the coefficient of determination ( $R^2$ ) in each gridcell, comparing the monthly LAI3g data to CLM4.5BGC and CLM-MOD to identify areas with strong agreement between the remotely sensed data and the models, and areas with weak relationships.

## 3 Results

### 3.1 Seasonal patterns in CLM

We found generally good agreement between LAI3g and CLM averaged across grass-dominated regions. In a comparison of monthly values from 1982 to 2010 for the single PFT dominated regions in Fig. 1,  $R^2$  values ranged from 0.54 to 0.9 (Table 2) with the majority of the grass  $R^2$  greater than 0.7. Figure 2 shows the monthly values across all years, and we see similar results – generally good correspondence, especially in seasonal pattern, between LAI3g and the CLM runs in the grass-dominated regions. The root mean squared error (RMSE) values in Table 2, as well as Fig. 2b and c show that CLM does not always capture the appropriate LAI values in grasslands, but the seasonal cycle is reasonably correct.

In contrast, CLM does not successfully capture phenological patterns or values in areas dominated by woody drought deciduous vegetation. Among tropical deciduous trees CLM predicted LAI appears to be both too high and out of phase with the satellite

[Interactive Discussion](#)

same Latin hypercube approach to determine the best fitting values for this parameter (Fig. 5). This additional leaf-on criterion, set so that 20 mm of rain must accumulate over 10 days in order for leaf onset to occur, led to a removal of the “brown season” leaf out in CLM (dashed green line in Fig. 3) without preventing two green seasons per year, as is possible in some semi-arid regions (e.g. parts of Ethiopia, Fig. 3e).

### 3.3 Global simulations

To test how well the additional rainfall parameter performed globally, we ran CLM with the new rainfall parameter for 45 years (CLM-MOD) from the same equilibrium base-line state as was used in the first run described. Measures of maximum LAI (Fig. 6) and mean LAI (data not shown) in CLM-MOD showed closer matches to LAI3g than CLM4.5BGC. While CLM values remain far too high in the evergreen tropics, the maximum LAI values did increase appropriately in CLM-MOD to better match the LAI3g data in deciduous savanna regions.

To test whether the poor fit between CLM and LAI3g was due to multiple annual LAI peaks in CLM we counted the number of peaks per year in each data set (Fig. 7). We found that in the observations, only areas in the humid tropics had multiple peaks in the LAI3g data (“peaks” in these cases being relatively small fluctuations), while CLM showed multiple peaks per year throughout many of the savanna regions of the world. CLM-MOD has more areas with only one peak, particularly in Sub-Saharan Africa.

We compared monthly data and mapped the point-wise coefficients of determination ( $R^2$ ) globally to consider how well CLM LAI seasonality matched the LAI3g dataset (Fig. 8a). There were moderate to good relationships ( $R^2 > 0.4$ ) in the higher latitudes for the standard model, but notably poorer relationships in the lower latitudes, particularly in savanna regions. In contrast, a comparison between LAI3g and CLM-MOD showed improvements in savanna regions, with the most dramatic improvements in Sub-Saharan Africa (Fig. 8b). Predicting the phenology of the Brazilian Cerrado continues to be a challenge in CLM-MOD, shifting from two peaks in CLM4.5BGC to no

peaks in CLM-MOD, but the heterogeneity revealed in the LAI3g dataset suggests that this region may need closer consideration and a separate phenology algorithm.

## 4 Discussion

### 4.1 Comparing LAI3g to CLM LAI

5 By comparing the satellite LAI3g data to output from CLM4.5BGC we found that while the model performed reasonably well in temperate grasslands both in seasonal cycle and in magnitude, it performed poorly in areas of tropical grasslands, mixed grassland and drought deciduous trees (savannas) and areas dominated by drought deciduous trees. Closer examination of individual gridcells in tropical regions revealed that these points often have a leaf flush during the dry season in the model, which is not the case in the satellite data, or in reality. This additional leaf flush not only impacts the phenological cycle, but also affects the overall amount of carbon stored in plants and their maximum LAI, as plants spend their stored carbon unnecessarily in the dry season, leaving less carbon available during the wet season for growing leaves. This addition of leaf carbon in the dry season also may affect the fire cycle in varying ways around the dry tropics. While these runs of the model were not coupled to a dynamic atmosphere, we expect that this dry season leaf flush could also impact the climate, potentially having an unrealistic cooling effect by moving more water in to the atmosphere during what should be a very dry time of year, but also darkening the land surface, possibly leading to a slight warming.

20 The mechanism behind the dry season leaf flush is an increase in soil water potential in the dry season to levels above the prescribed leaf-out threshold. These increases derive from the assumption that all of the land surface in CLM sits on top of an unconfined aquifer. In most cases this aquifer is either irrelevant because plenty of soil water is available or it is essential to plant survival in areas where aquifers do exist in the real world. In semi-arid systems, however, this extra pool of soil water becomes problematic

in the dry season. The top soil layers dry out due to soil evaporation and, when plants are active, evapotranspiration, establishing a water potential gradient, which causes water to be transferred by mass flow from the aquifer up through the soil column to the shallow soil layers, until eventually the moisture potential reaches the trigger for plants to leaf out. Per the drought deciduous phenology algorithm, once leaf out is triggered it must be completed, so plants begin to grow leaves but then the increased evapotranspiration rate quickly draws the soil moisture down below leaf off threshold levels, so leaf drop begins again, typically as soon as the leaf out period (30 days) has ended. The degree to which aquifers in reality contribute to dry season evapotranspiration is largely unconstrained because there are no global data sets for depth to water table, making it impossible to non-arbitrarily define where plants should have access to ground water and where they should not. Refinements of the soil water algorithms in CLM and access to new data sources like the NASA Soil Moisture Active Passive mission (SMAP; Entekhabi et al., 2014) will likely improve this part of the model, but like many aspects of the CLM, more global-scale data is needed.

### 4.2 Soil water and rainfall in CLM

To address the erroneous dry season leaf flush we tested a number of different model alterations, beginning with the least invasive – adjusting existing parameters – and ending with adding an additional rule to the existing drought deciduousness algorithm. We experimented with four alternative methodologies for triggering leaf onset, described below, but for brevity we have only shown results from the last and most effective approach.

First, we considered that using the third soil layer in CLM may be an arbitrary choice of soil depth, and that usage of the soil moisture potential derived drought index (“BTRAN”, Oleson and Lawrence, 2013), which is weighted by vertical root fraction across the whole rooting depth profile, might provide a more physiologically relevant metric and be less prone to increases due to upwards moisture diffusion in the dry season. However, since the exponential root profile in the CLM weights the top soil

the rainfall accumulated over the last 10 days should be higher than a threshold value (20 mm). Thus, if soil moisture rose above the threshold level, but little or no rain had fallen, plants would not put on leaves. The new model performs better both for the point simulations and in global simulations, both in terms of the seasonal cycle of LAI, where the average point-wise coefficient of determination ( $R^2$ ) between modelled and observed monthly satellite LAI of drought deciduous dominated points (> 50 % drought deciduous cover) is significantly higher for the new model (0.31 vs. 0.13).

### 4.3 Impacts of modifications to the model

This relatively small change to the drought deciduous phenology algorithm had wide ranging impacts within CLM. Because carbon was not being unnecessarily spent to grow leaves during the dry season, which was then not replenished since there was not enough water to maintain photosynthesis, CLM-MOD showed substantially higher overall carbon stores in savanna regions (Fig. 10, blue lines). Over time, this increase in vegetation carbon could lead to more realistic soil carbon levels, which have been shown to be too low in savanna regions in CLM (Wieder et al., 2013).

Fire is a critical component of savanna ecology and has been a focus of recent efforts to improve the CLM (Li et al., 2014). Our change to the drought deciduous phenology algorithm does have an impact on the fire cycle, but unfortunately, though not surprisingly, it degrades the fire model's performance relative to a global fire data set (GFED4; Giglio et al., 2013). Comparing the average total annual fire fractions for each gridcell with drought deciduous cover greater than 50 % across the time period for which we have both GFED4 data and CLM output (1996–2010) we find a correlation between GFED4 and CLM4.5BGC of 0.35 (global correlation = 0.44), and a correlation of 0.23 with CLM-MOD (global correlation = 0.33). This degradation of fire model performance is not surprising, however, given that the fire model was developed using CLM4.0CN with the erroneous dry season green up and a different forcing dataset. As shown in Fig. 9, fraction of area burned per gridcell decreases in many areas in CLM-MOD, likely due to the fact that less fuel is being produced in the dry season, and seasonality shifts

as well (Fig. 10, red lines). Future work will include exploring the impacts of this change to CLM on fire and other ecosystem properties.

Two other outstanding questions about LAI in CLM remain. First, in savanna regions in the CLM LAI drops to zero during the dry season, implying that across an entire gridcell all vegetation is perfectly drought deciduous (Figs. 3–6). Reality is, of course, far more complex, as reflected in the LAI3g dataset which rarely drops below 1.0 in savanna regions. The focus of this study was on improving the timing and magnitude of peak LAI, however, improving dry season values is also a concern. This is a deeper question in the CLM, as it relates to the overall land cover data. It is possible, for example, that there is evergreen vegetation in these gridcells, while the land cover classification determines that all gridcells with a significant seasonal LAI signal are 100% “drought deciduous”. Even if drought deciduous and evergreen vegetation types did not co-exist in the same ecosystem type, within gridcell spatial heterogeneity might also allow their coexistence within a whole gridcell (e.g. riparian areas or areas with shallow ground water that are able to stay green year round). Second, though also not the focus of this study, it is clear from Fig. 6 that across the mesic regions of the terrestrial biosphere CLM is dramatically overestimating LAI. This issue, often masked when only mean annual values or zonal means are considered, deserves more attention, and it is likely that recent detailed studies of carbon allocation (e.g. Doughty et al., 2014) could improve this part of the model.

A question also remains as to whether our new representation of leaf phenology, in spite of its improved performance, constitutes a better predictive model of current and future ecosystem behavior. In general, we hope to construct ecosystem models that represent hypotheses of how plants function, that we might test against observations. In this case, we find that the existing hypothesis – that plants respond to the soil water potential of the upper soil – does not adequately represent phenological patterns. However, this explanation is complicated because the predictions depend also on the properties of soil water in the model. Given a perfect representation of soil moisture, we might find that the existing leaf-on hypothesis is a good approximation of average

vegetation behavior. However, at present the coupling of these two complex systems produces unexpected results. By tying the vegetation behavior to the actual climate drivers we are reducing the complexity of the problem, however, we are also reducing the capacity of the model to be responsive to the nuances of climate drivers. For example, the same rainfall amount in high and low humidity regimes will have different impacts on net soil moisture.

Ideally, models should represent the mechanisms by which ecological processes operate in as much fidelity as we understand. The representation of drought phenology is interesting; however, as we suspect that there are many different phenological strategies in the tropics that the CLM classifies with the same algorithm (e.g. Archibald and Scholes, 2007). This means that, in the absence of the representation of these numerous phenological strategies in the model, we are really representing the net behavior of ecosystems, rather than the exact mechanism pertaining to a single species. The fact that CLM-MOD improved model performance most significantly in Africa and less so in Australia and South America by some metrics (Fig. 7) suggests that evolutionary differences between plants could play a significant role in determining phenological patterns between continents. In a higher-fidelity land surface model, we might ideally allow numerous phenological algorithms to compete for light and water resources, and the ecosystem LAI profile would reflect the net behavior of the successful algorithms. This type of modelling is now theoretically possible (e.g. Fisher et al., 2010), and will be investigated in future versions of the CLM.

## 5 Conclusions

By comparing satellite derived estimates of LAI to LAI values produced by the latest version of the CLM we revealed a small but significant issue in the CLM – the tendency for leaves to flush during the dry season in drought deciduous PFTs due to unrealistic upwards movement of water through the soil column. We tested a number of different approaches to address this issue, however we found that tying leaf flushing to rainfall

directly produced results that best matched the satellite data. While this change to the drought deciduous phenology algorithm does not reflect our understanding of how plants respond to their environment in the real world, without better data on soil water movement at scales relevant to global land surface modeling it is difficult to rely on the soil water model to drive plant physiology. Changing the drought deciduous phenology algorithm to remove dry season leaf flushes improved overall LAI values in savanna systems as well as changed the amount of carbon stored in these systems and altered the fire cycle. Future work will include exploring different drought deciduous phenology algorithms for different PFTs and testing the importance of this change in a coupled Earth system model.

*Acknowledgements.* The authors thank the members of the Terrestrial Sciences Section at NCAR for helpful discussions of this work, and we thank Ranga Myneni and his group for providing the LAI3g dataset. K. M. Dahlin was funded by an Advanced Study Program Postdoctoral Fellowship at NCAR. We would also like to acknowledge high-performance computing support from Yellowstone (ark:/85065/d7wd3xhc) provided by NCAR's Computational and Information Systems Laboratory, sponsored by the National Science Foundation.

## Environmental drivers of drought deciduous phenology in the Community Land Model

K. M. Dahlin et al.

**Figure 10.** Seasonal cycles of rainfall ( $\text{mm day}^{-1}$ ; gray bars), total vegetation carbon ( $\text{g C m}^{-2}$ ; blue lines), and gridcell burned fraction ( $\text{day}^{-1}$ ; red lines) in CLM4.5BGC and CLM-MOD for one year (2001).
