Abstract

The CEFLES2 campaign during the Carbo Europe Regional Experiment Strategy was designed to provide simultaneous airborne measurements of solar induced fluorescence and CO_2 fluxes. It was combined with extensive ground-based quantification of

5   leaf- and canopy-level processes in support of ESA's Candidate Earth Explorer Mission of the "Fluorescence Explorer" (FLEX). The aim of this campaign was to test if fluorescence signal detected from an airborne platform can be used to improve estimates of plant mediated exchange on the mesoscale. Canopy fluorescence was quantified from four airborne platforms using a combination of novel sensors: (i) the prototype

10   airborne sensor AirFLEX quantified fluorescence in the oxygen A and B bands, (ii) a hyperspectral spectrometer (ASD) measured reflectance along transects during 12 day courses, (iii) spatially high resolution georeferenced hyperspectral data cubes containing the whole optical spectrum and the thermal region were gathered with an AHS sensor, and (iv) the first employment of the high performance imaging spectrometer HY-

15   PER delivered spatially explicit and multi-temporal transects across the whole region. During three measurement periods in April, June and September 2007 structural, functional and radiometric characteristics of more than 20 different vegetation types in the Les Landes region, Southwest France, were extensively characterized on the ground. The campaign concept focussed especially on quantifying plant mediated exchange

20   processes (photosynthetic electron transport, CO_2 uptake, evapotranspiration) and fluorescence emission. The comparison between passive sun-induced fluorescence and active laser-induced fluorescence was performed on a corn canopy in the daily cycle and under desiccation stress. Both techniques show good agreement in detecting stress induced fluorescence change at the 760 nm band. On the large scale, airborne

25   and ground-level measurements of fluorescence were compared on several vegetation types supporting the scaling of this novel remote sensing signal. The multi-scale design of the four airborne radiometric measurements along with extensive ground activities fosters a nested approach to quantify photosynthetic efficiency and gross primary pro-

ductivity (GPP) from passive fluorescence.

1 Introduction

Photosynthesis harvests light from a variable stream of solar photons and converts this energy to carbohydrates that fuel all plant processes and ultimately life on Earth. The efficiency of photosynthetic electron transport and carbon fixation is highly regulated, depending on plant species and environmental constrains (Rascher and Nedbal, 2006; Schurr et al., 2006). Quantum efficiency of photosystem II (PSII) depends primarily on light intensity and varies between 0.83 at leaves of dark adapted higher plants to close to zero at high light intensities (Rascher et al., 2000). Plants have evolved a variety of photochemical and non-photochemical regulation mechanisms that are either constitutively active or are activated on demand to optimise the distribution of energy for photosynthesis and to avoid damage because of over-energetisation of metabolism (refer to Schulze and Caldwell, 1995, for a comprehensive summary). Thus, plant photosynthesis is dynamically regulated adapting to environmental conditions and being affected by the ecological plasticity of each species (Turner et al., 2003b; Schurr et al., 2006).

Remote sensing offers the unique possibility to derive spatially explicit information on vegetation status at local, regional or landscape scale (Goetz and Prince, 1999; Hilker et al., 2008). Reflectance signals alone, however, cannot quantify photosynthetic activity and dynamics of vegetation accurately. Great benefits would be expected from remote sensing techniques that quantify the actual status of photosynthetic carbon fixation. Monteith's (1972, 1977) mechanistic Light Use Efficiency (LUE) concept relates the photosynthetic capacity to LUE, describing the potential to convert absorbed radiation into biomass. Accordingly, Gross Primary Productivity (GPP) can be described as a function of the fraction of absorbed photosynthetic active radiation (f_{APAR}) and LUE (Turner et al., 2003a; Hilker et al., 2008). LUE is highly variable and depends on the phenological status, structure and species composition (Field et al., 1995; Goetz and

Prince, 1999). Due to its dynamic changes, the insufficient parameterization of LUE is identified as a major source of uncertainties in modeling GPP (Hilker et al., 2008; Running et al., 2000).

Chlorophyll fluorescence analyses are among the most powerful techniques to non-destructively quantify photosynthetic efficiency and non-photochemical energy dissipation in photosynthetically active organisms under laboratory conditions. At canopy and field scale, chlorophyll fluorescence emission is frequently considered to be employed as a complementary, high-capacity signal on vegetation dynamics (Papageorgiou and Govindjee, 2004). Sun-induced fluorescence can be obtained from remote sensing platforms. Several studies have shown that it is correlated with photosynthetic efficiency and thus may serve as a proxy to quantify photosynthetic efficiency (Flexas et al., 2000, 2002).

The chlorophyll fluorescence emitted by a leaf under natural sunlight is only 1–5% of the total reflected light at a specific wavelength. This makes it particularly difficult to quantitatively extract the fluorescence signal from remote sensing data. However, at certain wavelengths, the solar irradiance is absorbed in the solar or earth atmosphere (so-called Fraunhofer lines); thus, there is no or greatly reduced incoming radiation at the Earth's surface in these wavelengths (Plascyk, 1975). Solar irradiance exhibits three main absorption bands in the red and near infrared wavelength region: the $H\alpha$ line at 656.3 nm is due to hydrogen absorption in the solar atmosphere, whereas two bands at 687 (O_2-B) and 760 nm (O_2-A) are due to absorption by molecular oxygen in the terrestrial atmosphere. The O_2-A and O_2-B bands especially overlap with the chlorophyll fluorescence emission spectrum and, due to their widths, have the potential to be investigated from air- and space-borne platforms. Thus, they can be used for monitoring chlorophyll fluorescence emission under daylight excitation by the method of the Fraunhofer lines in-filling (Plascyck, 1975).

Several studies are currently under way to evaluate the accuracy with which sun-induced fluorescence can be used to quantify photosynthetic efficiency. With this paper we report the concept and first results from the CEFLES2 campaign that took

place in the context of the Carbo Europe Regional Experiment Strategy (CERES) between April and September 2007 in Southern France (see http://www.esa.int/esaLP/SEMQACHYX3F_index_0.html). This campaign combined state-of-the-art remote sensing with extensive field-based measurements to quantify the actual status of photosynthetic efficiency from the level of single leaves to a regional scale. The overarching goal was to better constrain and reduce uncertainties in modelling mesoscale carbon fluxes using fluorescence as a direct input parameter.

2 The integrated concept of CEFLES2: quantifying photosynthetic efficiency from leaf- to the regional scale

CEFLES2 was designed to provide extensive and spatially resolved validation of photosynthesis estimates based on remote sensing fluorescence measurements that can be obtained using airborne instrumentation. Validation data were provided by extensive ground measurements of plant mediated exchange processes (photosynthetic CO_2 uptake, evapotranspiration and water use efficiency), fluorescence features at the leaf and canopy scale, and by CarboEurope aircraft fleet that was operating during CERES experimental campaigns in Les Landes (France) in April and September 2007.

A multitude of vegetation specific ground measurements were acquired during three campaigns (April, June, and September 2007). These included structural parameters (leaf area index (LAI), canopy height or fractional cover (f_{cover}), biochemical characterizations (chlorophyll, water and dry matter content), physiological parameters (PAM fluorometry, gas exchange) and standard field spectroscopy. These more traditional measurements were complemented with novel set-ups aimed to quantify fluorescence at the canopy level. As species of major interest, winter wheat was chosen in April and corn in September. Additionally, investigations were expanded to rapeseed, grassland and pine in April, corn, potato, sunflower and pine in June and bean, kiwi, vine and oak forest in September. The intensive measurement site was Marmande during the whole CEFLES campaign. Further test sites were located in Clairac, Le Bray, Villeneuve-sur-

2223

Lot, and Saint Laurent du Bois.

2.1 Leaf-level: quantifying photosynthesis and fluorescence

2.1.1 PAM fluorometry to derive cardinal points of photosynthesis

Efficiency of light reactions of photosynthesis were measured on the level of single leaves using the miniaturized Fluorescence Yield Analyser (Mini-PAM) of H. Walz (Effeltrich, Germany) with a leaf clip holder described by Bilger et al. (1995) (Fig. 1a). Spot measurements of photosynthetic photon flux density (PPFD, $\lambda=380\,\mathrm{nm}$ to $710\,\mathrm{nm}$) were taken inside the measuring field by the micro-quantum sensor of the Mini-PAM. Effective quantum yield of PS II ($\Delta F/F_m'$) was calculated as $(F_m'-F)/F_m'$, where F is fluorescence yield of the light adapted sample and F_m' is the maximum light-adapted fluorescence yield when a saturating light pulse (800 ms duration, intensity $\approx 4000\,\mu\mathrm{mol\,m^{-2}\,s^{-1}}$) was superimposed on the prevailing environmental light levels. The apparent rate of photosynthetic electron transport (ETR) of photosystem II (PS II) was obtained as $\mathrm{ETR}=\Delta F/F_m'\cdot\mathrm{PPFD}\cdot0.5\cdot\alpha$, where the factor 0.5 assumes equal excitation of both photosystems; the absorption factor α was derived from leaf level optical measurements using an integrating sphere.

Light within the canopy constantly changed and showed patches of varying intensity. Thus, leaves were exposed to rapid changes in PPFD of various duration and intensity, which could not be determined analytically. $\Delta F/F_m'$ and ETR values dynamically adapt primarily to these changes in light intensity, but may also reflect manifold underlying physiological mechanisms. Additional parameters, such as maximum apparent electron transport rate ($\mathrm{ETR_{max}}$) and saturating photosynthetically active radiation can be derived from light-response curves. In general, measurements of light-response curves lead to a deeper insight into characteristic parameters of a plant species, which are not related to the momentary ambient light conditions, but rather to the ontogeny of a leaf and to the range of physiological plasticity of a plant. In order to obtain light response characteristics, about 100 randomly distributed spot measurements were

2224

recorded within a field and plotted over PPFD. Light dependency data plotted in such way were mathematically fitted using single exponential functions to quantify the characteristic cardinal points of photosynthesis (Rascher et al., 2000).

2.1.2 Measurement of fluorescence emission spectrum

Algorithms for fluorescence retrieval from airborne data require the characterization of the fluorescence emission spectrum at the leaf level. They were recorded under natural sun light conditions using a specially built spectro-fluorometer based on a HR2000+ spectro-radiometer (Ocean Optics) (Fig. 1h). This instrument used solar radiation as an excitation source. Solar radiation is filtered by a short pass blue filter and focused onto the leaf by a converging lens to compensate the attenuation of the filter.

The spectro-radiometer was calibrated spectrally and for linearity using a standard black body (LI-Cor 1800-02, NE, USA) and a Hg-Ar standard lamp (CAL-2000, Micropack, Germany).

Measurements were performed around solar noon and during overflights in April, June and September 2007 on grass, wheat, corn and bean leaves from the different experimental sites. Chlorophyll content and PPFD were systematically acquired with a chlorophyll-meter (SPAD-502, Minolta) and a quantum-meter.

2.1.3 Gas exchange measurements

Using the open gas-exchange system Li-6400 (Li-Cor, USA) photosynthetic characteristics, i.e., CO_2 assimilation rate (A), stomatal conductance to water vapor (G_S), transpiration rate (Tr) and intercellular CO_2 concentration (Ci), were recorded for actual PPFD in April. In September whole light curves allowed the estimation of e.g., A or Tr for saturating PPFD (A_{1800}, Tr_{1800}). Light response curves were measured using the LED light source Li-6400-02B (Li-Cor, USA). The irradiances used for the light response curve were 0, 80, 250, 600, 1200 and 1800 μmol (photons) m^{-2} s^{-1}.

Desiccation stress was performed on four individual plants. The CO_2/H_2O fluxes

2225

were measured as an integral signal from the central parts of leaves (investigated area 6 cm^2) on the 4th leaves from the top. The leaves were kept inside the assimilation chamber under constant CO_2 concentration (380±5 μmol CO_2 mol^{-1}), air humidity and leaf temperature (following ambient conditions) during the measurement. Air flow rate through the assimilation chamber was maintained at 500 μmol s^{-1}.

2.2 Canopy-level

2.2.1 Active laser induced fluorescence

Active fluorescence spectra of vegetation were recorded by using a hyperspectral Fluorescence LIDAR (FLIDAR) imaging system (Fig. 1c). This consists mainly of a Q-switched Nd:YAG laser, a 1 m focal length Newtonian telescope and a 300 mm focal length spectrometer coupled to an intensified, gated 512×512 pixels CCD detector. Imaging was carried out by scanning the target with a computer-controlled, motorized mirror. The FLIDAR prototype includes also a low power DPSS (Diode-Pumped Solid State) laser (emitting in the green) for geometrical referencing on the target.

The pulsed Nd:YAG laser excitation source can operate at 355 nm (triple frequency) or at 532 nm (double frequency), with pulse width of 5 ns, pulse energy of 8 mJ and 20 mJ for the UV and green excitation respectively, and a maximum repetition rate of 10 Hz. The laser beam divergence is 0.5 mrad with a starting beam diameter of 7 mm. Three folding high energy dielectric mirrors provide the excitation laser beam to be coaxial to the telescope. The telescope is a 25 cm diameter f/4 Newtonian reflector. The fibre bundle is composed by 50 quartz optical fibres with a core diameter of 100 μm. The far field of view is 1 mrad that corresponds to about 2 cm diameter circle spot at a distance of 20 m.

The spectral dispersion system is the flat field SpectraPro-2300i by Acton Research. This spectrometer has a crossed Czerny Turner layout, 300 mm focal length, f/4. The spectrometer is equipped with three dispersion gratings having 150, 600, and 2400 grooves mm^{-1}. The gratings provide a nominal dispersion of 21.2, 5.1 and

2226

$0.9\,nm\,mm^{-1}$, respectively. The detector is a gateable 512×512 pixel CCD (model PI MAX:512, Princeton Instruments/Acton) equipped with an intensifier (Unigen III Generation). The pointing and scan system for the hyperspectral imaging is obtained by a movable folding mirror placed between the telescope and the target. This mirror is mounted in a controllable motorized fork that permits the rotation on two orthogonal axes. The primary axis is fixed and coaxial with the telescope and crosses the geometrical centre of the folding mirror surface. The secondary axis direction is set by the rotation of the first one, coplanar with mirror surface and crossing its geometrical centre. The used stepping motors give rotation accuracy better than 0.5 mrad.

Two different field set-ups of the FLIDAR were used to take measurements on vegetation: the first one, adopted during the April campaign, relied on the use of 4 mirrors positioned at 45° at about 1 m above the canopy (Fig. 1b). Wheat fluorescence was excited at 355 nm and detected in the 570–830 nm and 348–610 nm spectral windows. The 4 canopy zones (560 cm^2 each) were covered by scanning the motorized mirror, placed near the optical sensor that was mounted inside a van. A 10×10 sampling grid (~100 points per zone) was adopted and a spectrum was obtained by averaging 30 spectra per point.

The second one, adopted during the September CEFLES2 campaign, used a scanning mirror positioned on the top of a 6 m high scaffolding tower (Fig. 1d). This configuration, with the mobile mirror at about 2.7 m above the canopy, permitted to cover 1 m^2 area of the corn field within small angles from nadir. A reference fluorescent plastic target (Walz, Effeltrich, Germany, about 10×10 cm^2 of size) was positioned on the top-left corner of the scanned area; its fluorescence signal was acquired once per area scan, and used to normalize the fluorescence spectra of the scanned area. The van with the laser was located about 10 m from the scaffolding tower.

In both set-ups, the canopy average temperature was continuously measured and logged by means of a Minolta Land Cyclops optical pyrometer mounted either in proximity of the four 45° mirrors (Fig. 1b) or on top of the scaffolding tower (Fig. 1d).

2.2.2 Passive sun-induced fluorescence

Sun-induced fluorescence (Fs) was estimated in the field with four different set-ups. Three stationary set-ups exploit field spectrometers to collect the signal above the canopy during the day and differ for the spectral resolution achieved. While the first one was manually operated, the second and third system operated autonomously. In addition to the stationary approaches, a mobile set-up was used to quickly measure the distribution of canopy fluorescence and thus cover the spatial distribution of the F_S signal.

(1) The core of the first set-up was composed by two HR4000 spectrometers (OceanOptics, USA). One spectrometer covered the visible to near-infrared part of the spectrum (350–1100 nm) with a Full Width at Half Maximum (FWHM) of 2.8 nm while a second spectrometer was limited to a narrower spectral range in the near-infrared (720–800 nm) to provide a very high spectral resolution (0.13 nm FWHM) intended for fluorescence retrieval at the O_2-A band. The canopy was observed from nadir by bare fibres (25° field of view). The manual rotation of a mast mounted horizontally on a tripod permitted to observe either the white reference panel or the canopy. The spectrometric set-up was installed over winter wheat in April and over corn in September to record canopy diurnal cycle of optical properties and sun-induced fluorescence (Fig. 1f refers to the set-up used in the September over corn).

Prior to the field campaign, both spectrometers were radiometrically calibrated with known standards. The spectroscopy technique referred to as "single beam" (Milton and Rolling, 2006) was applied in the field to evaluate the incident and upwelling fluxes: target measurements are "sandwiched" between two white reference measurements (calibrated panel, Optopolymer GmbH, Germany) taken a few seconds apart. For every acquisition, 15 and 4 scans (for the two spectrometers, respectively) were averaged and stored as a single file. Additionally, a dark current measurement was collected for every set of acquisitions (four consecutive measurements). Spectrometers were housed in a Peltier thermally insulated box (model NT-16, Magapor, Zaragoza, Spain)

keeping the internal temperature at 25°C in order to reduce dark current drift.

Processing of raw data included correction for CCD detector non linearity, correction for dark current drift, wavelength calibration and linear resampling; radiance calibration, incident radiance computation by linear interpolation of two white reference panel measurements, and computation of vegetation optical indices and sun-induced fluorescence according to Meroni and Colombo (2006).

(2) A second high performance spectro-radiometer set-up (SpectroFLEX) for detecting passive fluorescence signal has been installed at Villeneuve-sur-Lot (Lat. 44.397571°, Long.: 0.763944°) during April 2007, in the middle of a large and homogeneous field of natural grass (Fig. 1e). The objective was to compare passive fluorescence data acquired with the airborne AirFLEX sensor and ground based measurements recorded with the SpectroFLEX sensor on the same target. The target was composed mainly of Velvetgrass (*Holcus lanatus)*, an erectophil monocot species of about 60 cm height.

SpectroFLEX is based on a narrow band spectrometer (HR2000+, Ocean Optics, USA). The instrumental function of 0.2 nm FWHM was established using the atomic lines of a spectral calibration lamp (Cal-2000-Bulb, Micropack, Germany) also used for wavelength calibration. Radiometric calibration has been performed with a black body lamp (Li-Cor 1800-2, Lincoln, NE, USA). A high pass filter (Schott RG590) prevented for stray light. The spectro-radiometer was enclosed in a temperature regulated box at 25±0.5°C, allowing thermal noise reproducibility. A shutter (Inline TTL shutter, Micropack, Germany) allows CCD dark current acquisition for each integration time. All the electronic components were protected by a waterproof aluminium box. Fluorescence fluxes were simultaneously acquired in both O_2-B band (687 nm) and O_2-A band (760 nm), similar to the AirFLEX sensor. Fluorescence was computed using the same channel widths and positions as the AirFLEX sensor inboard the Seneca airplane. SpectroFLEX has been designed to measure automatically over extended periods of time (days or weeks).

Measurements at the canopy level required a nadir viewing configuration. The in-

2229

strument box was installed at the top of a 2.5 m scaffolding. A 2 m length optical fibre connects the sensor head to the spectrometer. The entrance of the optical fibre is fixed above the target by a 1 m horizontal arm at 2.4 m above the ground (Fig. 1e). The resulting target diameter is about 1.1 m, which ensures a good spatial integration of the canopy structure. Local irradiance was measured using a white frosted PVC board which intercepts alternately the field of view of the sensor. This reference board was periodically moved by an electromagnet. Radiances measured with the reference board were used to estimate the photosynthetic active radiation after calibration against a quantum meter (SDEC, France). An elementary measurement cycle requires the acquisition of two spectra on the target and two spectra on the reference. The acquisition frequency is up to 0.4 Hz at maximum illumination.

(3) A FieldSpec Pro high resolution spectroradiometer (Analytical Spectral Devices, Boulder, USA), which was used to quantify canopy fluorescence. The device measures reflected radiation within the spectral domain of 350–2500 nm with a nominal bandwidth of 1.4 nm (350–1050 nm) and a field-of-view (FOV) of 25°. A calibrated Spectralon[TM] panel (25×25 cm) served as white reference to estimate incident irradiance.

The instrument's fibre optic was mounted on a robotic arm of 0.6 m length, approximately 1 m above the canopy. The movement of the robotic arm allowed to automatically collect daily cycles of four different spots with a circular area of about 0.5 m diameter each (Fig. 1g). The acquired dataset consists of spectral records from four canopy areas, bracketed by measurements of the reference panel. At each position, a trigger signal released the recording of 10 single spectra. Each spectrum was internally averaged by the spectrometer from 25 individual measurements. Integration time was automatically optimized during the day in order to maximize the instrument signal to noise ratio. In June and September five diurnal courses were acquired during the campaign windows. The fluorescence signal was quantified using the modified FLD method proposed by Maier et al. (2003) in the O_2-A band.

(4) Several FieldSpec Pro high resolution spectroradiometers were used for a spatially explicit characterization of the fluorescence signal over a wide range of agricultural

2230

crops and surface classes. During the three campaigns in April, June, and September 11 different crops were characterized, whereas one representative field per crop was selected (exceptionally winter wheat with seven fields and corn with eight fields). Beside these agricultural canopies, water and bare soil were measured. To cover the spatial heterogeneity of each field, four representative places were selected and three measurements per place were performed.

At each place in the field, the instrument's fibre optic was mounted on a tripod, approximately 1 m above the canopy. Three different spots with a circular area of 0.5 m diameter each were recorded moving the fibre optic manually over the canopy. The fluorescence signal was quantified as mentioned in set-up 3.

2.2.3 Quantifying sun-induced fluorescence using the Fraunhofer Line Discrimination

Under natural sunlight illumination, chlorophyll a exhibits a fluorescence emission spectrum in the red and near-infrared regions (600–800 nm), characterized by two peaks at about 690 and 740 nm. Solar light is reflected by vegetation in the same spectral region (Fig. 2) and, therefore, the signal reaching a remote sensor is composed by the superimposition of the two fluxes: fluorescence and background reflection from the surface.

In laboratory conditions, one can somehow decouple the two signals by selecting two non overlapping wavelengths for illumination and observation of the sample: a shorter excitation wavelength induces fluorescence which is observed at longer wavelength without any reflection background (e.g. Corp et al., 2006). This concept has been also successfully adapted for outdoor application using a pulsed laser as light source for measuring the so-called laser induced fluorescence (see Sect. 2.2.1). However, this approach cannot be currently considered for satellite observations because it requires a strong laser pulse that limits its application to the near range.

Fluorescence quantification from the far range must rely on passive measurements (i.e. without the use of an artificial excitation source) to decouple the small fluorescence signal from the background reflectance. This goal can be achieved by selectively mea-

suring the flux upwelling from vegetation in specific spectral lines characterised by very low levels of incident irradiance (i.e. Fraunhofer lines).

In such lines, the otherwise much stronger reflectance background is significantly reduced, and fluorescence can be decoupled from the reflected signal. In particular, two of these lines (O_2-B and O_2-A positioned at 687 and 760 nm, due to oxygen absorption in the earth atmosphere) largely overlap with the chlorophyll fluorescence emission spectrum of plants and have often been exploited for fluorescence retrieval (e.g. Moya et al., 1999, 2004; Evain et al. 2001; Louis et al., 2005; Meroni et al., 2008; Middleton et al., 2008).

Fluorescence is estimated in correspondence of these spectral lines by using the FLD (Fraunhofer Line Discrimination) method originally proposed by Plascyck (1975). In short, this method compares the depth of the line in the solar irradiance spectrum to that of the line in the radiance spectrum up-welling from vegetation. Fluorescence is quantified by measuring to what extent this depth is reduced by fluorescence in-filling.

In operation, fluorescence can be decoupled from the reflected signal when measuring in spectral channels close enough so that it can be assumed that both reflectance and fluorescence vary smoothly with wavelength. Therefore, FLD relies on spectral measurements inside and outside narrow Fraunhofer lines, in which incident irradiance is strongly reduced.

The FLD basic concept has been recently upgraded with several modifications and improvements by different research groups (e.g. Gomez-Chova et al., 2006; Meroni and Colombo, 2006; Alonso et al., 2008) in order to increase the accuracy of the method and to exploit the current availability of hyperspectral high resolution data (for a review of fluorescence retrieval method see Meroni et al., 2009).

2.3 Field to regional level using novel airborne sensors

On the largest spatial scale, a fleet of several aircrafts was employed over the region, testing different approaches to quantify sun-induced fluorescence from airborne platforms (Fig. 3).

2.3.1 Repeated transects using AirFLEX

AirFLEX is an interference-filter based airborne sensor developed in the framework of the Earth Observation Preparatory Programme of the European Space Agency (Fig. 3a–c). Basically it is a six channel photometer aimed to measure the in-filling of the atmospheric O_2 bands. A set of 3 different channels (each with a specific interference filter) is used to characterize each absorption band: one at the absorption peak and two others immediately before and after the O_2 absorption feature. The peak positions of these filters (Omega Optical, Brattleboro, VT, USA) are 685.541, 687.137 and 694.114 nm for the O_2-B band and 757.191, 760.39 and 770.142 nm for the O_2-A band (L1 to L6, respectively, Fig. 2 bottom). The FWHM are 0.5 nm and 1.0 nm for the O_2-B and O_2-A band respectively. In order to maintain stability of the characteristics of these filters, the filter compartment was insulated and warmed up to $40\pm0.1°$C. The use of two filters out of the band allows interpolating the reflectance within the band. In addition to the narrow band filters, long pass coloured filters (Schott RG645) in combination with a baffled hub are used to reduce the stray light.

The AirFLEX sensor was fixed on the floor of the Piper Seneca airplane of the IBIMET (Fig. 3b). During data acquisition a synchronised video camera recorded the images of the context and a spectroradiometer measured the radiance of the target in the spectral range of 200–890 nm. A proprietary program developed under LABVIEW 7 (National Instrument) software allows for real time control and display of measured signals. AirFLEX has been calibrated radiometrically, with a calibration source (Li-Cor 1800-02, NE, USA). The spectral calibration was done with an HR4000 spectrometer (Ocean Optics, IDIL, France) and 6035 Hg(Ar) lamp (Oriel Instruments, France). The foot print on the ground is about 10×15 m at a repetition rate of 5 Hz. The entire CEFLES2 campaign totalised 14 flights performed by the Seneca aircraft with the AirFLEX sensor onboard, which represent a ground sampling of about 6000 km. AirFLEX generated several products including (i) fluorescence radiances at 687 and 760 nm, (ii) fluorescence fractions at the same wavelengths obtained by dividing fluorescence

<center>2233</center>

radiances by the reflected radiance at 687 nm, (iii) the Photochemical Reflectance Index (PRI, Gamon et al., 1992) and (iv) the Normalized Differential Reflectance Index (NDVI). A commercial thermal camera (Flir, mod. SC500) was installed together with AirFLEX providing surface temperature information coregistered with fluorescence data (Fig. 3c).

2.3.2 Repeated transects using an airborne hyperspectral sensor in the METAIR-DIMO aircraft.

The small research aircraft of Metair AG (Switzerland) was used as platform for hyperspectral measurements. Alongside an extensive range of additional parameters such as CO_2, H_2O, CO, NO_x, (Neininger, 2001; Schmitgen et al., 2004) were captured simultaneously. The flight track and attitude angles were recorded by a TANS Vector phase sensitive GPS system blended with 3-axis accelerometers. For the collection of hyperspectral reflectance data, a portable sensor (FieldSpec Pro, ASD Inc., Boulder, CO, USA) was mounted in the lefthand underwing pod (Fig. 3g). Reflected light was captured in nadir orientation with a fibre optic that was equipped with a 1° foreoptic. Incident light was spectrally analyzed in the range from 350 to 1050 nm, with a FWHM of 1.4 nm. The instrument was operated in continuous mode, thus spectra were collected with approximately 2 Hz. Spectral measurements were recorded using radiances and exposure time was adjusted to 130 ms for best signal to noise ratio and to avoid saturation. In order to improve data quality, three spectra were averaged and saved. The FieldSpec device generates a TTL trigger signal that was used (i) to record the time of each hyperspectral measurement and (ii) to capture a video image (640×480 pixels, 12-bit, grey values) using an industrial video camera (Flea, Point Grey Research, Vancouver, BC, Canada; with a 25 mm lens, Cosmicar/Pentax). Both camera and hyperspectral sensor share the same viewing orientation, but differ in their field of view (1° for the FieldSpec device and 10.5° for the video camera).

Data from the FieldSpec hyperspectral instrument are currently being processed according to the principle of Fraunhofer Line Discrimination. The same protocol for

<center>2234</center>

ground based and airborne data is used to test for the influence of atmospheric absorption and to establish a consistent data processing line from the canopy to the ecosystem level.

2.3.3 Regional mapping with the Airborne Hyperspectral Scanner (AHS)

The Airborne Hyperspectral Scanner (AHS) is an 80-bands airborne imaging radiometer (Fig. 3e), developed and built by SensyTech Inc., (currently Argon ST, and formerly Daedalus Ent. Inc.) and operated by the Spanish Institute for Aerospace Technology (INTA) in different remote sensing projects. It has 63 bands in the reflective part of the electromagnetic spectrum, 7 bands in the 3 to 5 μm range and 10 bands in the 8 to 13 μm region.

The AHS was first flown by INTA on September 2003. During 2004 the instrument was validated during a number of flight campaigns which included extensive ground surveys (SPARC-2004 and others), and is fully operational in INTA's C-212-200 EC-DUQ "Paternina" aircraft since beginning of 2005 (Fig. 3d). AHS has been configured with distinct spectral performances depending on the spectral region considered. In the VIS/NIR range, bands are relatively broad (28–30 nm): the coverage is continuous from 0.43 up to 1.0 μm. In the SWIR range, there is an isolated band centred at 1.6 μm with 90 nm width, simulate corresponding band in satellite missions.

Next, there is a set of continuous, fairly narrow bands (18–19 nm) between 1.9 and 2.5 μm, which are well suited for soil/geologic studies. In the MWIR and LWIR regions, spectral resolution is about 300 to 500 nm, and the infrared atmospheric windows (from 3 to 5 μm and from 8 to 13 μm) are fully covered. These spectral features allow to state that AHS is best suited for multipurpose studies/campaigns, in which a wide range of spectral regions including thermal have to be covered simultaneously.

2.3.4 First regional map of fluorescence derived from HYPER airborne imager

SIM.GA HYPER is a 512+256-spectral-band push-broom sensor with VNIR and SWIR imaging capability. The instrument was provided by Galileo Avionica. The airborne hyperspectral system covers the 400–2450 nm spectral region and was operated at 1000 m. The hyperspectral HYPER SIM.GA is composed of two optical heads (Fig. 3f):

1. VNIR Spectrometer with a spectral range of 400–1000 nm, 512 spectral bands with 1.2 nm spectral sampling, 1024 spatial pixels across a swath of 722 m, which corresponds to a pixel resolution of 0.7×0.7 m

2. SWIR Spectrometer with a spectral range of 1000–2450 nm, 256 spectral bands with 5.8 nm spectral sampling, 320 spatial pixels across a swath of 425 m, which corresponds to a pixel resolution of 1.33×1.33 m

The optical heads are managed by a common data acquisition and control electronics. The HYPER SIM.GA works as a push-broom imager. A spatial line is acquired at nadir and the image is made exploiting the aircraft movement. The optical head of HYPER SIM.GA is rigidly coupled to a GPS/INS unit that collects data about platform movements (yaw, roll, pitch, velocity, altitude, lat, long) allowing to geo-rectify the images acquired. The use of GPS/INS unit reduces the mass and the cost of the instrument avoiding stabilized platform.

These campaigns were the first employment of this new airborne hyperspectral instrument and we are currently establishing the processing routines for geometrical and radiometrical processing of the data. With this communication we present the first results, automated routines allowing the processing of the extensive data sets are currently developed.

3 Selected first results highlighting the dynamics of variations in photosynthetic energy conversion

3.1 Leaf-level: quantifying photosynthesis and fluorescence

3.1.1 Diurnal variations of photosynthetic efficiency

During the September campaign main focus was put on characterizing corn in the diurnal course. Leaf-level measurements showed a physiological limitation of photosynthesis during different times of the day. Photosynthetic efficiency was high during environmentally moderate morning hours, a clear depression of photosynthetic efficiency was obvious during afternoon, when conditions were dry and hot, and photosynthetic efficiency increased again towards the evening, when conditions again became moderate. Diurnal courses of sun-induced fluorescence yield of corn were derived from spectrometric measurements and their potential as proxies for LUE was investigated. GPP was modeled using Monteith's LUE-concept (Monteith, 1971, 1973) and GPP and LUE values were compared to synoptically acquired eddy covariance data. The diurnal response of complex physiological regulation of photosynthesis could be tracked from sun-induced fluorescence. Considering structural and physiological effects, this study showed for the first time that including sun-induced fluorescence improves modeling of diurnal courses of GPP. A detailed publication on this study is in press (Damm et al., 2009).

3.1.2 Activation of photosynthesis within days

During the April campaign special focus was put on winter wheat that was a main crop in the study area. Weather conditions at the beginning of the campaign were wet and cloudy and photosynthesis of the plants was adapted to the low light and moderate conditions. Midday 18 April 2007, weather changed and the whole region was abruptly exposed to longer lasting high pressure conditions with concomitant clear skies and

warm and dry air.

This poses good conditions for a test case: Photosynthesis of the formerly low-light adapted plants had to acclimate to the now high light conditions. This was a specific advantage to test if these dynamic physiological changes were reflected in sun-induced fluorescence.

PAM fluorometry was used to analyze changes in photosynthetic activity and condition of photosynthetic apparatus of winter wheat plants. Among other parameters, ETR of photosystem II, non-photochemical quenching (NPQ) and steady-state fluorescence were determined. To relate these three parameters, the variation of these parameters at saturating light intensities was investigated in detail. Plants increased their ETR in the course of acclimation to the high light period. The increase was strongest in the morning. However, acclimation was associated with increasing leaf temperatures. At the beginning of the improved weather conditions, the NPQ at saturating light intensities was lowest around midday, but increased with the days in high light conditions. Concomitantly, a slight decrease in potential quantum efficiency was observed. This could be the sign of photoinhibition or of activation of sustained photoprotection mechanisms, due to high light intensities over the days. In contrast, steady-state fluorescence showed an inverse behaviour. The relation of fluorescence with NPQ revealed a clear negative correlation, whereas fluorescence and ETR apparently were not correlated. No obvious correlation between NPQ and fluorescence with leaf temperature was observed. This suggests that fluorescence indeed is associated with properties describing the physiological status of photosynthesis and thus, may serve as a remote sensing measure to quantify changes of the efficiency of photosynthesis that occur on the relevant time scales. A detailed study of this topic will be published soon.

3.1.3 Characterization of sun-induced fluorescence emission spectrum at the leaf level

The shape of the fluorescence emission spectrum at the leaf level depends on many different parameters, such as the excitation wavelength, light intensity, pigment concen-

tration or leaf structure. Figure 4 compares sun-induced fluorescence emission spectra of leaves from different species under the same conditions of illumination (about 1700 μmol m^{-2} s^{-1}). It can be seen that leaves with the same chlorophyll content can show different emission spectra (e.g. wheat and bean). The shape parameters of the fluorescence emission spectrum are introduced into the retrieval algorithm of fluorescence from airborne data.

3.2 Canopy-level

Ground-based diurnal cycles of sun- and laser-induced canopy fluorescence were collected with the aim of characterizing the temporal dynamic of fluorescence in addition to the spatial variation captured by airborne sensors (Sect. 3.3).

3.2.1 Variations of sun-induced canopy fluorescence

Diurnal cycles of canopy sun-induced fluorescence were collected during both the April and September campaigns over natural grassland (Velvetgrass), winter wheat and corn, respectively.

The diurnal cycle of both fluorescence fluxes (F687 and F760) and Photosynthetic Active Radiation (PAR) during a sunny day is shown in Fig. 5a (21 April 2007) but similar results are obtained for other days (Fig. 5b). One may observe that F687 closely followed PAR whereas less diurnal variation was observed on F760. It is hypothesized that this difference, already observed in other experiments (Louis et al., 2005), is due to a canopy structure effect. Nevertheless the fluorescence ratio F687/F760 was calculated and compared with the same ratio calculated for the in board AirFLEX data (Table 1). On-board data were processed to retrieve the fluorescence flux at the ground level after atmospheric corrections, according to Daumard et al. (2007). Between 11:27 and 14:05, time of the airplane overpass, an increase of similar amplitude was observed on both on-board and ground measurements.

As another example, the diurnal variation of Fs at 760 nm over winter wheat, mea-

2239

sured at three days (22–24 April) under comparable meteorological conditions (i.e. clear sky) is shown in Fig. 5b. As it is generally observed for photosynthesis, Fs exhibited a diurnal variation which is partially driven by incident PPFD (i.e. the more photons are absorbed, the more are dissipated through Fs). However, while PPFD showed a symmetrical trend around solar noon, Fs reached its maximum before solar noon (about 12:00 UTC) and decreased after 13:00 UTC. This trend was more easily observable with the Normalized Fs (Fs yield, Fig. 5c), which is the yield of Fs per unit incident radiation (Meroni and Colombo, 2006). The diurnal course of Fs yield, which is expected to track the canopy LUE (e.g. Meroni et al., 2008), showed an increase during early morning, a depression during solar noon when the PPFD reached its maximum, followed by a recover in late afternoon.

3.2.2 Variations of sun-induced canopy fluorescence over different agricultural crops

Main focus of this analysis was to investigate the variability of sun-induced fluorescence within the same field, of the same crop, and in different canopies. Additionally, the interdependency between Fs and the well established Normalized Difference Vegetation Index (NDVI) was investigated. The measured crop types and surface classes provide a high gradient of canopy structural parameters and the plant physiological status.

A first relative evaluation of the data showed a hyperbolic relationship of the Fs signal and the NDVI (Fig. 6) for different crop types and surfaces. A clear difference in the intra- and inner-field variation was obvious for both parameters. Moreover, the sensitivity of both parameters differs especially at the boundaries of the parameter range. On the one hand, the classical vegetation index saturated in dense canopies (e.g. when LAI is higher than 4) at a value of 0.9, where Fs still provided a differentiation of values (e.g. for winter wheat). On the other, the NDVI showed a significant variability for non vegetated surface classes (e.g. bare soil or water), whereas Fs values were more consistent with values around 0 for such non vegetated surfaces. Given insights from these first experiments the focus of future analysis will be put on a differentiated view on the impact of structural and functional response to the acquired signal.

2240

3.2.3 Active laser induced fluorescence mapping

The corn fields investigated during the September campaign were characterized by a large variability in chlorophyll content within the canopy and heterogeneous chlorophyll concentrations along the longitudinal axis of single leaves. Consequently, the shape and intensity of the chlorophyll fluorescence spectra at leaf level were markedly dependent on the leaf position into the canopy (Fig. 7a) and on the part of the leaf measured (Fig. 7b), in accordance with the well-known relationship between chlorophyll content and fluorescence reabsortion at the red fluorescence band (Buschmann, 2007). Therefore, the fluorescence spectrum of the canopy was the result of heterogeneous contributions from the top layers as well as of those coming from the inner layers, which underwent multiple reabsorption processes.

An example of a laser induced fluorescence (LIF) mapping for a corn canopy is shown in Fig. 8. The LIF measurements were performed by the FLIDAR system that covered a $1\,m^2$ area (specifically, the area was about $80 \times 120\,cm$) of the corn field within small angles from nadir (Fig. 8a). The spot effectively measured with the FLIDAR system at each laser pulse was a circular area of 2.5 cm in diameter. The whole fluorescence spectrum between 580 and 830 nm was recorded for each spot. The spatial resolution, defined as the distance between the center of one measured spot and the next one, was about 4.5 cm both in the vertical and horizontal direction. The images consist of 18×27 pixels and each pixel value corresponds to the integral of the fluorescence spectrum, obtained as an average of 20 spectral measurements with 532 nm excitation, in the $760 \pm 2.5\,nm$ band. Measurements with very low fluorescence intensity at 680 nm (e.g. soil or dried vegetation) were marked as black pixels to exclude them from further analysis.

As expected, the fluorescence map was found to be largely heterogeneous. Although it was difficult to appreciate significant changes in the fluorescence evolution over the day, a general decrease of the F760 nm signal appeared (Fig. 8b–d). This variation was confirmed by the fluorescence signal, determined as average over the canopy

area. As shown in Fig. 9a, the fluorescence signals decreased in a magnitude of 15% from 08:00 to 15:00 CET. Similar results were obtained for a second diurnal course of the same corn canopy recorded on 15 September 2007 (data not shown).

3.2.4 Comparison between Sun Induced Fluorescence and Laser Induced Fluorescence

The comparison between Sun Induced Fluorescence (SIF) and Laser Induced Fluorescence (LIF) measurements at the canopy level is important to better understand variation of SIF within days and seasons. Furthermore, only few data sets concerning the relationship between active and passive chlorophyll fluorescence are reported into the literature (Moya et al., 2004; Liu et al., 2005; Pérez-Priego et al., 2005). In those studies, the active measurements were restricted to the leaf level, hence, they were limited for calibration purposes of canopy related SIF measurements.

In this study, canopy LIF data were compared to SIF data, which were acquired as described in Sect. 2.2.2. LIF-measurements were done within the same corn field in Marmande, at the same time but in a distance of few tenths of meters to the SIF-measuremets. Some corn plants were selected next to the control area and the water flow was interrupted by cutting their stem. The plants were fixated with poles to keep their original position. Leaf level gas-exchange measurements were used to track the desiccation stress.

The time courses of the normalized SIF signal at 760 nm, the LIF signal measured at the same wavelength, and maximum photosynthetic and transpiration rates (A_{1800} and Tr_{1800}) are shown in Fig. 9 for both the control and treated areas (stem cutting occurred at 09:30 UTC). In general, both SIF and LIF signals of the control canopies showed a trend to decrease with time. Afternoon decrease was evident for CO_2 assimilation rate, especially Tr_{1800} and LIF reacted similar. The decrease in the SIF was less evident, but still visible. This discrepancy is rather small considering the difference in the excitation light (wavelength and intensity) and in the excitation/detection geometry of the two measuring systems. The passive fluorescence data were largely dependent

on the solar-zenith angle that affects penetration of the excitation light into the canopy. Consequently, the contributions from leaves in the inner layers to the fluorescence signal can change with time and may not be adequately normalized by using the solar radiation incident on the horizontal plane. On the contrary, in the LIF measurements, the excitation/detection geometry was constant.

The average light intensity of the laser excitation at 532 nm was always less than half the incident solar PAR measured during the experiment (1100–1500 μmol m^{-2} s^{-1}), therefore, no marked perturbation of the leaf photosynthetic state was expected to be induced by the excitation beam.

Under desiccation stress, both LIF and SIF values showed a larger decrease during the day with respect to the controls (Fig. 9a). This trend was more evident in the ratio between control and stressed plant fluorescence signals (Fig. 9b). For both techniques, the difference in fluorescence between control and stressed plants increased with time. The decrease of A_{1800} in stressed plants was faster than the decreases in LIF and SIF values.

3.3 Regional level

3.3.1 Repeated transects using AirFLEX

Repeated transects using AirFLEX have been performed over an area of about 130 km by 80 km covered with various vegetation types such as winter wheat, corn, vineyard, fruit trees, grassland, oak forest, pine forest and also bare fields which are useful for calibration purpose. Figure 10 shows a map of these transects over some of the Marmande test fields (top). It also shows the corresponding fluorescence signals as well as the NDVI over three different fields covered with corn and bean (bottom). One can see a significant increase of NDVI between the first corn field and the bean field, while there were only little changes between the bean field and the second corn field. These observations could be related to the senescence of the first corn field that was observed from the video images (data not shown). It can be seen from Fig. 10b that many flu-

2243

orescence variations were correlated to NVDI variations. However, larger variations were observed on fluorescence signals. Fluorescence also showed variations from field to field that could not be explained by NDVI changes. It was the case of the F687 signal when going from the bean field to the second corn field. These fluorescence changes were most probably related to different canopy structure, as bean is a dicot with a rather planophile structure while corn is a monocot having a more erectophile structure. Similar results have been already reported in Moya et al. (2006).

To investigate spatial and temporal variability of fluorescence signals at a wider spatial scale, an analysis based on a number of target fields along the flight track was performed. Portions of land belonging to specific land use and land cover classes were identified and parameterized, by visual inspection of the video images acquired during the flights. Each field was marked and basic statistical computations were computed from the fluorescence signal. In total, 40 fields were identified over pine forest, and 42 over winter wheat land uses, besides smaller amounts of fields over other land use classes. Fields had similar and homogeneous characteristics, in terms of texture and NDVI. Mean NDVI was computed from the flights is 0.83±0.07 over pine and 0.87±0.08 over wheat. Not all the fields were sampled in all the flights, because of track variations between different flights. Nevertheless, investigating the aggregated fluorescence response over these fields can provide information on the spatial and temporal variability of the observations, and on the absolute magnitudes of fluorescence signals at a wider scale with respect to point observations. Figure 11 shows the diurnal course of the fluorescence flux over pine and wheat fields respectively, together with incoming PPFD. Variability related to differences between fields is encompassed by vertical deviation bars. Both fluorescence signals showed a diurnal shape that obviously was driven by incoming radiation, but important differences in fluorescence signals over different land cover exist; fluorescence was on average 53% higher on wheat then on pine forest, while corresponding average incoming PPFD, as directly measured at the time of observations, did not show any remarkable difference. Even in absence of direct canopy-scale LUE measurements over target fields, LUE of a fast developing winter

2244

wheat canopy in April was expected to be higher than LUE over mature pine forests, suggesting that Fs can potentially explain LUE spatial variability when compared at different areas. The influences and the relative importance of structural effects on the fluorescence radiometric signals are not yet well known and may play a role in explaining part of this observed variability.

3.3.2 First regional map of fluorescence derived from HYPER airborne imager

The spatial analysis of the fluorescence signal by means of imaging spectroscopy data is complex. The signal recorded by airborne line scanners with a relatively large field-of-view varies strongly across the track, i.e. perpendicular to the flight direction, due to a variety of disturbing effects (e.g. Kennedy et al., 1997; Schiefer et al., 2006). With regard to the derivation of the fluorescence signal the following effects have to be considered: (1) data from push-broom sensors like HYPER are influenced by shifts in the position and width of spectral bands. This view-angle variation is known as "smile effect"; (2) atmospheric scattering in the NIR regions vary with path length between sensor and Earth surface and increases towards larger view-angles; (3) anisotropic surface reflectance that are a function of the fractions of sunlit and shaded surfaces are driven by the direction of incoming solar irradiance and position of the sensor (Pinty et al., 2002). All these effects require special attention when the raw data is transferred into surface reflectance and a normalization of such effects has to be included into radiometric calibration and atmospheric correction. Moreover, knowledge on the directionality of the fluorescence signal as emitted by canopies is still very limited and possible influences cannot be estimated at the moment.

First attempts to compute reliable reflectance values from the HYPER images showed a high degree of statistical noise and problems with the radiometric calibration because of bad pixels and uneven radiometric response of the sensor. The across track gradients caused be the smile effect appear to be dominant (Fig. 12, top). Therefore, it was not feasible to derive fluorescence in physical values. As alternative we used an empirical normalization to account for most of the disturbing effects and rel-

ative fluorescence values. This empirical normalization used the fact, that the across track effects also exist in soil data, which may be used as reference during the FLD method. For normalization bare soil surfaces were manually selected in the image. The spectral information from these soil surfaces was then used to derive an average soil signal for each viewing angle. By incorporating this varying signal, the FLD was set up as a function of view angle and normalized fluorescence values were derived for the entire image. In doing so, the requirement of the reference signal being viewed under identical illumination conditions as the target signal (Moya et al., 2004) was met. However, differences in the directional behaviour of soils and vegetation, as well as knowledge gaps on the directionality of emitted fluorescence limit the accuracy and an evaluation of absolute fluorescence value is not feasible with this empirical approach.

Nevertheless, it was possible to evaluate the spatial distribution of fluorescence and to achieve first insights on the spatial variations of fluorescence (Fig. 12, bottom). Clear differences in intra- and inner-field variation of the fluorescence signal were observed for agricultural areas near Marmande. Differences correlate to some extent with traditional index-based proxies for vegetation or with vegetation fractions derived from spectral mixture analyses. However, such index-based measures often saturate at values where fluorescence still allows differentiating photosynthetic activity. Moreover, the absolute fluorescence signal differed clearly between different crop types having the same leaf area, providing information that cannot be derived by traditional measures.

4 Conclusions

Current satellite remote sensing techniques do not have the potential to quantify the actual status of photosynthetic light conversion and light use efficiency (LUE) is thus not implemented as an operational input parameter in current carbon models. The fluorescence signal is to date the most power full signal that is directly related to actual photosynthetic efficiency. With this paper we demonstrated the potential, but also the open questions to measure fluorescence from the leaf to the mesoscale. We also

showed a path how this directly measured signal can be used for a better estimate of leaf and ecosystem carbon fixation and potentially evapotranspiration. Several campaigns and scientific studies are currently under way to better understand the link between sun-induced fluorescence and variations in photosynthetic carbon fixation and to explore the technical feasibility to detect the signal accurately from a space born platform. These conditions were strongly supported by the FLEX mission as one of ESA's candidate missions for a future Earth Explorer (Rascher, 2007). Fluorescence definitely shows potential as a direct measure of actual photosynthesis, nevertheless, we do not underestimate the challenges especially that of scaling up leaf-level methods to the canopy level. The plant canopy is a complex three-dimensional structure that changes due to environmental factors and structural adaptations of the plants.

Fig. 1.

2253

Fig. 1. Ground measurement set-up to quantify changes of photosynthetic efficiency from the leaf to the canopy level. **(A)** Mini-PAM measurement within winter wheat. Fluorescence emission and photosynthetic quantum efficiency is characterized with this fast screening method at hundreds of representative leaves under the prevailing environmental conditions. **(B)** Mirror set-up of the active FLIDAR imaging system as they were installed in April in winter wheat. **(C)** FLIDAR imaging system of the group of G. Agati. The laser system was installed inside a van variably targeting mirrors in the field. **(D)** computer controlled movable mirror of the active FLIDAR imaging system as they were installed in September a few meters above a corn canopy. **(E)** The SpectroFLEX set up for passive fluorescence measurements in the O_2-B (687 nm) and O_2-A (760 nm) bands. The number of bands, widths and central wavelengths have been chosen similar to those of the AirFLEX airborne sensor. The scaffolding was in the middle of a large grassland field in which several acquisition points by the AirFLEX sensor were possible. The target was Velvetgrass (*Holcus Lanatus*), an erectophile monocot species of about 60 cm height. The averaged chlorophyll concentration was 27 μg cm^{-2}. **(F)** Schematic drawing of the passive measurements set-up (1) in Sect. 2.2.2. **(G)** Spectrometric set-up (3) explained in Sect. 2.2.2. An automated arm constantly moved the fibre optics of a FieldSpec system between the reflectance standard and three spots of vegetation. Installation above corn in September. The same, cross-calibrated detector was used airborne (Fig. 3a). **(H)** Spectrofluorometer for measurement of sun-induced fluorescence emission spectra.
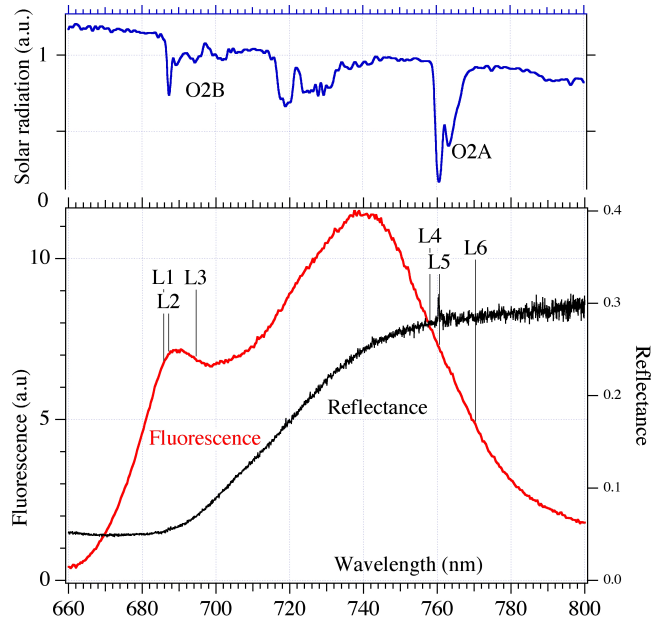

2254

Fig. 2. Top: Solar spectrum showing the O_2 bands at the spectral resolution of the AirFLEX sensor. Bottom: Red and near-infrared region of the fluorescence emission spectrum after full sun light adaptation of a Velvetgrass leaf. Sun-induced fluorescence was measured with the special instrument described in Sect. 2.1.3. The reflectance spectrum has been superimposed. It was acquired at the canopy level with the SpectroFLEX set-up. The positions of the central wavelengths (Li) of the six channels of the AirFLEX sensor are also shown. These spectra were required to retrieve the fluorescence by the FLD principle.

2255
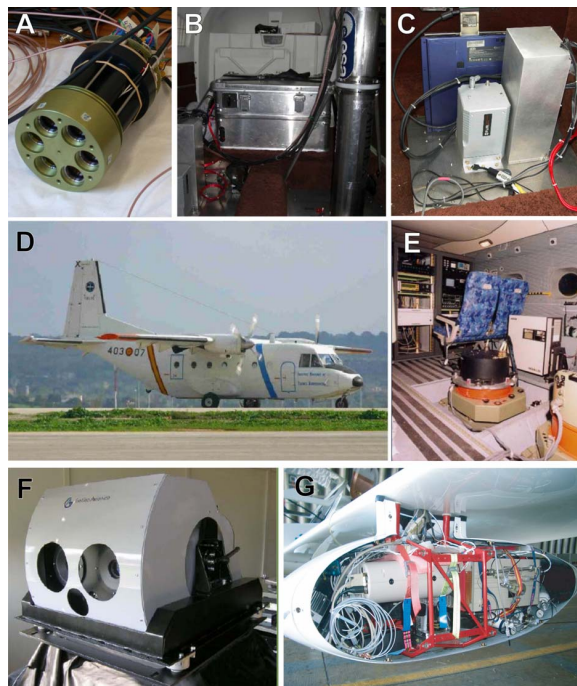

Fig. 3.

Fig. 3. Airborne instruments that were employed during the campaign to quantify changes of photosynthetic efficiency from the field to the regional level. **(A)** Internal sensor head of the Air-FLEX sensor showing the six channels for O_2-A and O_2-B fluorescence retrieval. Each channel requires three spectral bands: within the atmospheric absorption feature and on the left and right shoulder of the absorption feature. **(B)** Picture of AirFLEX installed on board the CNR SENECA during the campaigns. **(C)** Thermal camera on board the SENECA. **(D)** INTA C-212-200 EC-DUQ "Paternina" aircraft. Within this aircraft both the AHS and HYPER sensor were installed for parallel recording of flight lines. **(E)** AHS hyperspectral imager onboard EC-DUQ "CASA" as arranged during the CEFLES 2 campaign. **(F)** Picture of the SIM.GA HYPER sensor, which was first time used during the CEFLES2 campaign. **(G)** Underwing pod with the Field-Spec hyperspectral reflectance instrument. The instrument continuously acquired spectra with 2 Hz resolution along repeated overpasses during the campaign. The same, cross-calibrated detector was used on the ground (Fig. 1h).

2257
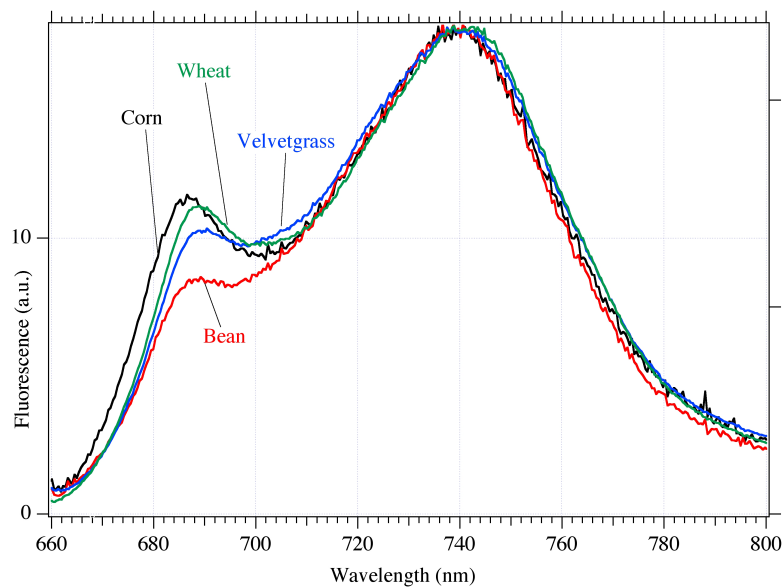

Fig. 4. Variability of sun-induced fluorescence emission spectra after light adaptation (1700 μmol photons m^{-2} s^{-1}). Adaxial sides of leaves from four species were measured with the special instrument described in Sect. 2.1.3. Chlorophyll content (μg cm^{-2}): Corn 48, Bean 42.2, Velvetgrass 27.1, Wheat 41.9.
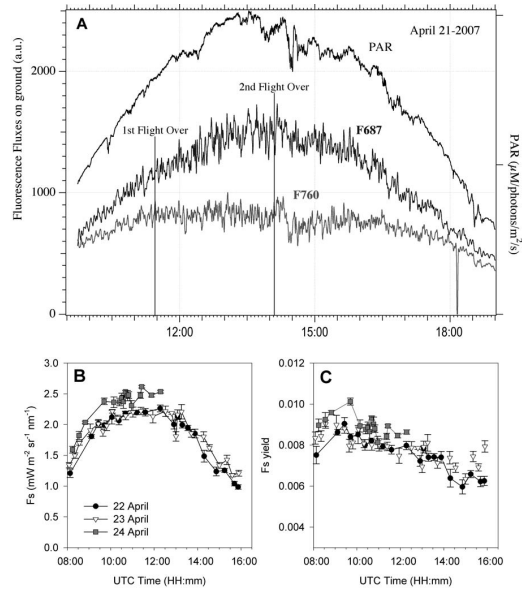

2258

Fig. 5. (A) Diurnal course of fluorescence fluxes at 687 and 760 nm, (F687 and F760) and Photosynthetic Active Radiation (PAR), measured at the canopy level with the SpectroFLEX set-up. Similar results were obtained on 22 and 23 April 2007. Vertical black lines indicates the moment at which the field has been flight over. The fluorescence ratios inboard and at ground level are compared in Table 1. **(B)**, **(C)** Diurnal courses of sun-induced fluorescence (Fs) and normalized Fs (Fs yield) at 760 nm measured over three measurement days. Values represent mean±SE (n=4 consecutive measurements). Measurements were collected over a winter wheat dense canopy (LAI=6.3 m^2 m^{-2}) during three days of measurements (22–24 April 2007) at the Marmande main site.

2259
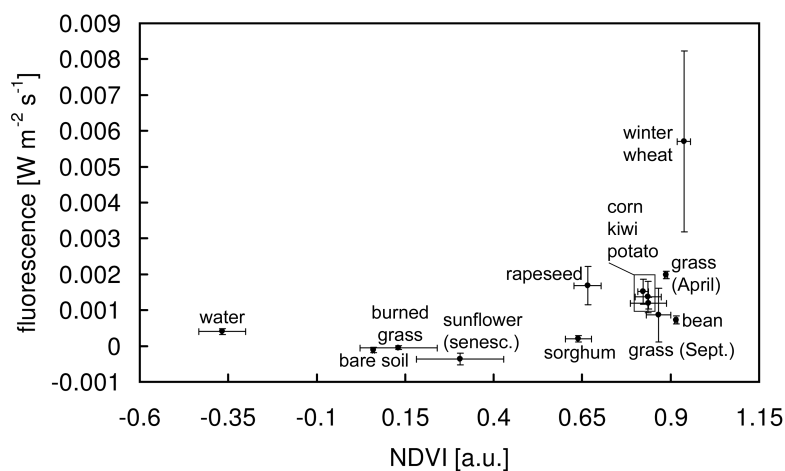

Fig. 6. Sun-induced fluorescence and NDVI over different 11 agricultural crops and two additional surface classes. For each canopy type, average and standard deviation of 12 single measurements were calculated (winter wheat 84, corn 96).
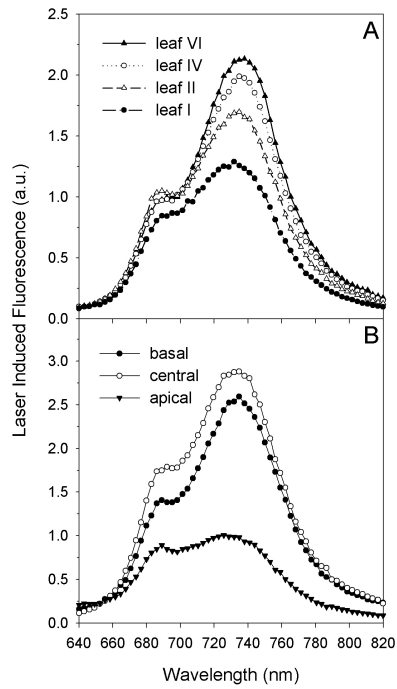

Fig. 7. Laser induced fluorescence spectra of single corn leaves excited at 532 nm. **(A)** leaves at different position into the plant (I to VI from top of the plant). **(B)** Different part from the same leaf (leaf II from the top).
Fig. 8. **(A)** Corn canopy area (about 1 m^2) scanned by the FLIDAR imaging system, within small angles from nadir; note the presence of a fluorescence standard (blue) and a reflectance standard (white) at the left-top corner. **(B–D)** Canopy fluorescence maps at the 760 nm band, with excitation at 532 nm, acquired in sequence at 08:00, 10:30 and 15:00 UTC, respectively, on 12 September 2007. Each map, made up of 18×27 pixels, required an acquisition time of 20 min. Fluorescence intensities in the colour bar are expressed as arbitrary units.

**Fig. 9.** Time evolution of photosynthetic CO_2 uptake rate **(A)**, leaf transpiration **(B)**, SIF and LIF signals at 760 nm **(C)** and ratio of the fluorescence signals **(D)** from control and stressed corn plants. Desiccation stress was applied at 10:00 UTC by cutting the plants but keeping them under the same conditions in the canopy. Photosynthetic uptake rates and transpiration were measured at the leaf level, while SIF and LIF were measured on the canopy level (about 1×1 m). LIF and SIF data were normalized to a fluorescence standard signal and to the incident solar radiance, respectively.
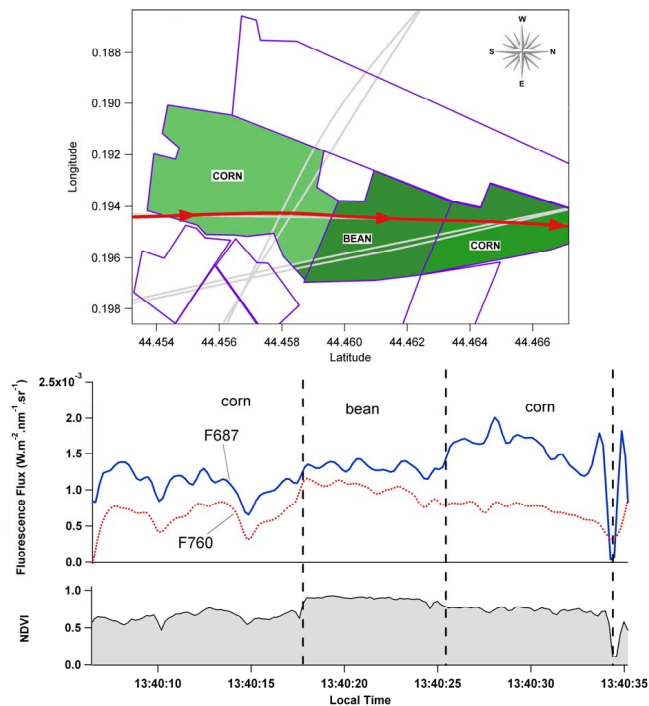

2263

Fig. 10. Top: AirFLEX transects over the Marmande test fields on 15 September 2007. Bottom: Fluorescence flux at 687 nm, fluorescence flux at 760 nm and NDVI measured during the transect marked in red.
Fig. 11. Fs (left axis) and PPFD (right axis) averages at different hours of the day over 118 pine fields (black circles) and over 47 wheat fields (white circles) during five days of flights from 18–23 April 2007.
2265

Fig. 12. Relative distribution of Fs signal as derived from HYPER imaging spectroscopy data (30 June 2007) without correction of anisotropic cross-track effects (top) and with empirical correction of the effects (bottom). Results show Fs values for all corn fields in the Marmande area and have been filtered with a 3×3 pixel mean filter to reduce statistical noise.
