The ocean is a substantial source of nitrous oxide (N₂O) to the atmosphere, but little is known on how this flux might change in the future. Here, we investigate the potential evolution of marine N₂O emissions in the 21st century in response to anthropogenic climate change using the global ocean biogeochemical model NEMO-PISCES. Assuming nitrification as the dominant N₂O formation pathway, we implemented two different parameterizations of N₂O production which differ primarily at low oxygen (O₂) conditions. When forced with output from a climate model simulation run under the business-as-usual high CO₂ concentration scenario (RCP8.5), our simulations suggest a decrease of 4 to 12% in N₂O emissions from 2005 to 2100, i.e., a reduction from 4.03 to 3.71 to 3.54 / 3.56 TgN yr⁻¹ depending on the parameterization. The emissions decrease strongly in the western basins of the Pacific and Atlantic oceans, while they tend to increase above the Oxygen Minimum Zones (OMZs), i.e., in the Eastern Tropical Pacific and in the northern Indian Ocean. The reduction in N₂O emissions is caused on the one hand by weakened nitrification as a consequence of reduced primary and export production, and on the other hand by stronger vertical stratification, which reduces the transport of N₂O from the ocean interior to the ocean surface. The higher emissions over the OMZ are linked to an expansion of these zones under global warming, which leads to increased N₂O production associated primarily with denitrification. While there are many uncertainties in the relative contribution and changes in the N₂O production pathways, the increasing storage seems unequivocal and determines largely the decrease in N₂O emissions in the future. From the perspective of a global climate system, the averaged feedback strength associated with the projected decrease in oceanic N₂O emissions amounts to around -0.009 W m⁻²K⁻¹, which is comparable to the potential increase from terrestrial N₂O sources. However, the assessment for a compensation between the terrestrial and marine feedbacks calls for an improved representation of N₂O production terms in fully coupled next generation of Earth System Models.
Nitrous oxide (N$_2$O) is a gaseous compound responsible for two key feedback mechanisms within the Earth’s climate. First, it acts as a long-lived and powerful greenhouse gas (Prather et al., 2012) ranking third in anthropogenic radiative forcing after carbon dioxide (CO$_2$) and methane (CH$_4$) (Myrhe et al., 2013). Secondly, the ozone (O$_3$) layer depletion in the future might be driven mostly by N$_2$O after the drastic reductions in CFCs emissions start to show their effect on stratospheric chlorine levels (Ravishankara et al., 2009). The atmospheric concentration of N$_2$O is determined by the natural balance between sources from land and ocean and the destruction of N$_2$O in the atmosphere largely by photolysis (Crutzen, 1970; Johnston, 1971). The natural sources from land and ocean amount to ~6.6 and 3.8 TgN yr$^{-1}$, respectively (Ciais et al., 2013). Anthropogenic activities currently add an additional 6.7 TgN yr$^{-1}$ to the atmosphere, which has caused atmospheric N$_2$O to increase by 18% since pre-industrial times (Ciais et al., 2013), reaching 325 ppb in the year 2012 (NOAA ESRL Global Monitoring Division, Boulder, Colorado, USA, http://esrl.noaa.gov/gmd/).

Using a compilation of 60,000 surface ocean observations of the partial pressure of N$_2$O (pN$_2$O), Nevison et al. (2004) computed a global ocean source of 4 TgN yr$^{-1}$, with a large range of uncertainty from 1.2 to 6.8 TgN yr$^{-1}$. Model derived estimates also differ widely, i.e., between 1.7 and 8 TgN yr$^{-1}$ (Nevison et al., 2003; Suntharalingam et al., 2000). These large uncertainties are a consequence of too few observations and of poorly known N$_2$O formation mechanisms, reflecting a general lack of understanding of key elements of the oceanic nitrogen cycle (Gruber and Galloway, 2008; Zehr and Ward, 2002), and of N$_2$O in particular (e.g., Zamora et al., 2012, Bange et al., 2009 or Freing et al., 2012, among others). A limited number of interior ocean N$_2$O observations were made available only recently (Bange et al., 2009), but they contain large temporal and spatial gaps. Information on the rates of many important processes remains insufficient, particularly in natural settings. There are only few studies from a limited number of specific regions such as the Arabian Sea, Central and North Pacific, Black Sea, the Bedford Basin and the Scheldt estuary, which can be used to derive and test model parameterisations (Mantoura et al., 1993; Bange et al., 2000; Elkins et al., 1978; Farias et al., 2007; Frame and Casciotti, 2010; Westley et al., 2006; Yoshida et al., 1989; Punshon
N$_2$O is formed in the ocean interior through two major pathways and consumed only in oxygen minimum zones through denitrification (Zamora et al., 2012). The first production pathway is associated with nitrification (conversion of ammonia, NH$_4^+$, into nitrate, NO$_3^-$), and occurs when dissolved O$_2$ concentrations are above 20 µmol L$^{-1}$. We subsequently refer to this pathway as the high-O$_2$ pathway. The second production pathway is associated with a series of processes when O$_2$ concentrations fall below ~5 µmol L$^{-1}$ and involve a combination of nitrification and denitrification (hereinafter referred to as low-O$_2$ pathway) (Cohen and Gordon, 1978; Goreau et al., 1980; Elkins et al., 1978). As nitrification is one of the processes involved in the aerobic remineralization of organic matter, it occurs nearly everywhere in the global ocean with a global rate at least one order of magnitude larger than the global rate of water column denitrification (Gruber, 2008). A main reason is that denitrification in the water column is limited to the OMZs, which occupy only a few percent of the total ocean volume (Bianchi et al., 2012). This is also the only place in the water column where N$_2$O is being consumed.

The two production pathways have very different N$_2$O yields, i.e., fractions of nitrogen-bearing products that are transformed to N$_2$O. For the high-O$_2$ pathway, the yield is typically rather low, i.e., only about 1 in several hundred molecules of ammonium escapes as N$_2$O (Cohen and Gordon, 1979). In contrast, in the low-O$_2$ pathway, and particularly during denitrification, this fraction may go up to as high as 1:1, i.e., that all nitrate is turned into N$_2$O (Tiedje, 1988). The relative contribution of the two pathways to global N$_2$O production is not well established. Sarmiento and Gruber (2006) suggested that the two may be of equal importance, but more recent estimates suggest that the high-O$_2$ production pathway dominates global oceanic N$_2$O production (Freing et al., 2012).

Two strategies have been pursued in the development of parameterizations for N$_2$O production in global biogeochemical models. The first approach builds on the importance of the nitrification pathway and its close association with the aerobic remineralization of organic matter. As a result the production of N$_2$O and the consumption of O$_2$ are closely tied to each other, leading to a strong correlation between the concentration of N$_2$O and the apparent oxygen utilization (AOU). This has led to the development of two sets of parameterizations, one based on concentrations, i.e., directly...
as a function of AOU (Butler et al., 1989) and the other based on the rate of oxygen utilization, i.e. OUR (Freing et al., 2009). Additional variables have been introduced to allow for differences in the yield, i.e., the ratio of N₂O produced over oxygen consumed, such as temperature (Butler et al., 1989) or depth (Freing et al., 2009). In the second approach, the formation of N₂O is modeled more mechanistically, and tied to both nitrification and denitrification by an O₂ dependent yield (Suntharalingam and Sarmiento, 2000; Nevison et al., 2003; Jin and Gruber, 2003). Since most models do not include nitrification explicitly, the formation rate is actually coupled directly to the remineralization of organic matter. Regardless of the employed strategy, all parameterizations depend to first order on the amount of organic matter that is being remineralized in the ocean interior, which is governed by the export of organic carbon to depth. The dependence of N₂O production on oxygen levels and on other parameters such as temperature only acts at second order. This has important implications not only for the modeling of the present-day distribution of N₂O in the ocean, but also for the sensitivity of marine N₂O to future climate change.

Over this century, climate change will perturb marine N₂O formation in multiple ways. Changes in productivity will drive changes in the export of organic matter to the ocean interior (Steinacher et al., 2010; Bopp et al., 2013) and hence affect the level of marine nitrification. Ocean warming might change the rate of N₂O production during nitrification (Freing et al., 2012). Changes in carbonate chemistry (Bindoff et al., 2007) might cause changes in the C:N ratio of the exported organic matter (Riebesell et al., 2007), altering not only the rates of nitrification, but also the ocean interior oxygen levels (Gehlen et al., 2011). Finally, the expected general loss of oxygen (Keeling et al., 2010; Cocco et al., 2012; Bopp et al., 2013) could substantially affect N₂O production via both nitrifier denitrification and classic denitrification.

Ocean biogeochemical models used for IPCC’s 4th assessment report estimated a decrease between 2% and 13% in primary production (PP) under the business-as-usual high CO₂ concentration scenario A2 (Steinacher et al., 2010). A more recent multi-model analysis based on the models used in IPCC’s 5th assessment report also suggest a large reduction of PP down to 18% by 2100 for the RCP8.5 scenario (Bopp et al., 2013). In these simulations, the export of organic matter is projected to decrease between 6% and 18% in 2100 (Bopp et al., 2013), with a spatially distinct pattern: in general, productivity and
export are projected to decrease at mid- to low-latitudes in all basins, while productivity and export are projected to increase in the high-latitudes and in the South Pacific subtropical gyre (Bopp et al., 2013). A wider spectrum of responses was reported regarding changes in the ocean oxygen content. While all models simulate decreased oxygen concentrations in response to anthropogenic climate change (by about 2 to 4% in 2100), and particularly in the mid-latitude thermocline regions, no agreement exists with regard to the hypoxic regions, i.e., those having oxygen levels below 60 µmol L\(^{-1}\) (Cocco et al., 2012; Bopp et al., 2013). Some models project these regions to expand, while others project a contraction. Even more divergence in the results exists for the suboxic regions, i.e., those having O\(_2\) concentrations below 5 µmol L\(^{-1}\) (Keeling et al., 2010; Deutsch et al., 2011; Cocco et al., 2012; Bopp et al., 2013), although the trend for most models is pointing towards an expansion. At the same time, practically none of the models is able to correctly simulate the current distribution of oxygen in the OMZ (Bopp et al., 2013). In summary, while it is clear that major changes in ocean biogeochemistry are looming ahead (Gruber, 2011), with substantial impacts on the production and emission of N\(_2\)O, our ability to project these changes with confidence is limited.

In this study, we explore the implications of these future changes in ocean physics and biogeochemistry on the marine N\(_2\)O cycle, and make projections of the oceanic N\(_2\)O emissions from year 2005 to 2100 under the high CO\(_2\) concentration scenario RCP8.5. We analyze how changes in biogeochemical and physical processes such as net primary production (NPP), export production and vertical stratification in this century translate into changes in oceanic N\(_2\)O emissions to the atmosphere. To this end, we use the NEMO-PISCES ocean biogeochemical model, which we have augmented with two different N\(_2\)O parameterizations, permitting us to evaluate changes in the marine N\(_2\)O cycle at the process level, especially with regard to production pathways in high and low oxygen regimes. We demonstrate that while future changes in the marine N\(_2\)O cycle will be substantial, the net emissions of N\(_2\)O appear to change relatively little, i.e., they are projected to decrease by about 10% in 2100.

2. Methodology

2.1 NEMO-PISCES Model
Future projections of the changes in the oceanic N₂O cycle were performed using the PISCES ocean biogeochemical model (Aumont and Bopp, 2006) in offline mode with physical forcings derived from the IPSL-CM5A-LR coupled model (Dufresne et al., 2013). The horizontal resolution of NEMO ocean general circulation model is 2° x 2° cos Ø (Ø being the latitude) with enhanced latitudinal resolution at the equator of 0.5°. PISCES is a biogeochemical model with five nutrients (NO₃, NH₄, PO₄, Si and Fe), two phytoplankton groups (diatoms and nanophytoplankton), two zooplankton groups (micro and mesozooplankton), and two non-living compartments (particulate and dissolved organic matter). Phytoplankton growth is limited by nutrient availability and light. Constant Redfield C:N:P ratios of 122:16:1 are assumed (Takahashi et al., 1985), while all other ratios, i.e., those associated with chlorophyll, iron, and silicon (Chl:C, Fe:C and Si:C) vary dynamically.

2.2 N₂O parameterizations in PISCES

We implemented two different parameterizations of N₂O production in NEMO-PISCES. The first one, adapted from Butler et al. (1989) follows the oxygen consumption approach, with a temperature dependent modification of the N₂O yield (P.TEMP). The second one is based on Jin and Gruber (2003) (P.OMZ), following the more mechanistic approach, i.e., it considers the different processes occurring at differing oxygen concentrations in a more explicit manner.

The P.TEMP parameterization assumes that the N₂O production is tied to nitrification only with a yield that is at first order constant. This is implemented in the model by tying the N₂O formation in a linear manner to O₂ consumption. A small temperature dependence is added to the yield to reflect the potential impact of temperature on metabolic rates. The production term of N₂O, i.e., $J^{P.TEMP}(N₂O)$, is then mathematically formulated as:

$$J^{P.TEMP}(N₂O) = (γ + θ T ) J(O₂)_{consumption}$$  (1)

where $γ$ is a background yield ($0.53 \times 10^{-4}$ mol N₂O/mol O₂ consumed), $θ$ is the temperature dependency of $γ$ ($4.6 \times 10^{-6}$ mol N₂O (mol O₂⁻¹ K⁻¹)), $T$ is temperature (K),
and $f(O_2)_{\text{consumption}}$ is the sum of all biological O$_2$ consumption terms within the model. The same ratio between constants $\gamma$ and $\theta$ is used in the model as in the original formulation from Butler et al. (1989). Although this parameterization is very simple, a recent analysis of N$_2$O observations supports such an essentially constant yield, even in the OMZ of the Eastern Tropical Pacific (Zamora et al., 2012).

The P.OMZ parameterization, formulated after Jin and Gruber (2003), assumes that the overall yield consists of a constant background yield and an oxygen dependent yield. The former is presumed to represent the N$_2$O production by nitrification, while the latter is presumed to reflect the enhanced production of N$_2$O at low oxygen concentrations, in part driven by denitrification, but possibly including nitrification as well. This parameterization includes the consumption of N$_2$O in suboxic conditions. This gives:

$$J^{P.OMZ}(N_2O) = (\alpha + \beta f(O_2)) f(O_2)_{\text{consumption}} - k N_2O$$

(2)

where $\alpha$ is, as in Eq.(1), a background yield (0.9 $\times$ 10$^{-4}$ mol N$_2$O/mol O$_2$ consumed), $\beta$ is a yield parameter that scales the oxygen dependent function (6.2 $\times$ 10$^{-4}$), $f(O_2)$ is a unitless oxygen-dependent step-like modulating function, as suggested by laboratory experiments (Goreau et al., 1980) (Fig. S1, Supplementary Material), and $k$ is the 1$^{st}$ order rate constant of N$_2$O consumption close to anoxia (zero otherwise). For $k$, we have adopted a value of 0.138 yr$^{-1}$ following Bianchi et al. (2012) while we set the consumption regime for O$_2$ concentrations below 5 $\mu$mol L$^{-1}$. The constant $\alpha$ is in the same order of magnitude as the one proposed by Jin and Gruber (2003), while $\beta$ is two orders of magnitude smaller. The use of the original value would result in a significant increase of N$_2$O production associated with OMZs and, hence, in a departure from the assumption of dominant nitrification.

The P.OMZ parameterization permits us the independent quantification of the N$_2$O formation pathways associated with nitrification and those associated with low-oxygen concentrations (nitrification/denitrification) and their evolution in time over the next century. Specifically, we consider the source term $\alpha f(O_2)_{\text{consumption}}$ as that associated with the nitrification pathway, while we associated the source term $\beta f(O_2) f(O_2)_{\text{consumption}}$ with the low-oxygen processes (Fig. S2, Supplementary Material).

N$_2$O production is inhibited by light in the model, and therefore N$_2$O production in P.TEMP and P.OMZ parameterizations only occurs below a fixed depth of 100m.
We employ a standard bulk approach for simulating the loss of N$_2$O to the atmosphere via gas exchange. We use the formulation of Wanninkhof et al. (1992) for estimating the gas transfer velocity, adjusting the Schmidt number for N$_2$O and using the solubility constants of N$_2$O given by Weiss and Price (1980). We assume a constant atmospheric N$_2$O concentration of 284 ppb in all simulations to explore future changes inherent to ocean processes without feedbacks due to changes in the atmosphere.

2.3 Experimental design

NEMO-PISCES was first spun up during 3000 years using constant pre-industrial dynamical forcings fields from IPSL-CM5A-LR (Dufresne et al., 2013) without activating the N$_2$O parameterizations. This spin-up phase was followed by a 150-yr long simulation, forced by the same dynamical fields now with N$_2$O production and N$_2$O sea-to-air flux embedded. The N$_2$O concentration at all grid points was prescribed initially to 20 nmol L$^{-1}$, which is consistent with the MEMENTO database average value of 18 nmol L$^{-1}$ below 1500m (Bange et al., 2009). During the 150-yr spin-up, we diagnosed the total N$_2$O production and N$_2$O sea-to-air flux and adjusted the $\alpha$, $\beta$, $\gamma$ and $\theta$ parameters in order to achieve a total N$_2$O sea-to-air flux in the two parameterizations at equilibrium close to 3.85 TgN yr$^{-1}$ (Ciais et al., 2013). In addition, the relative contribution of the high-O$_2$ pathway in the P.OMZ parameterization was set to 75% of the total N$_2$O production based on Suntharalingam et al. (2000), where a sensitivity model analysis on the relative contribution of high- and low-O$_2$ production pathways showed that a higher contribution of nitrification (75%) than denitrification (25%) achieved the best model performance compared to the data product from Nevison et al. (1995). P.TEMP can be considered as 100% nitrification, testing in this way the hypothesis of nitrification as the dominant pathway of N$_2$O production on a global scale. Nitrification could contribute with up to 93% of the total production based on estimations considering N$_2$O production along with water mass transport (Freing et al., 2012).

Projections in NEMO-PISCES of historical (from 1851 to 2005) and future (from 2005 to 2100) simulated periods were done using dynamical forcing fields from IPSL-CM5A-LR. These dynamical forcings were applied in an offline mode, i.e. monthly means of
temperature, velocity, wind speed or radiative flux were used to force NEMO-PISCES. Future simulations used the business-as-usual high CO$_2$ concentration scenario (RCP8.5) until year 2100. Century scale model drifts for all the biogeochemical variables presented, including N$_2$O sea-to-air flux, production and inventory, were removed using an additional control simulation with IPSL-CM5A-LR pre-industrial dynamical forcing fields from year 1851 to 2100. Despite the fact that primary production and the export of organic matter to depth were stable in the control simulation, the air-sea N$_2$O emissions drifted (an increase of 5 to 12% in 200 yr depending on the parameterization) due to the short spin-up phase (150 yrs) and to the choice of the initial conditions for N$_2$O concentrations.

3. Present-day oceanic N$_2$O

3.1 Contemporary N$_2$O fluxes

The model simulated air-sea N$_2$O emissions show large spatial contrasts, with flux densities varying by one order of magnitude, but with relatively small differences between the two parameterizations (Fig. 1a and 1b). This is largely caused by our assumption that the dominant contribution (75%) to the total N$_2$O production in the P.OMZ parameterization is the nitrification pathway, which is then not so different from the P.TEMP parameterization, where it is 100%. As a result, the major part of N$_2$O is produced in the subsurface via nitrification, contributing directly to imprint changes into the sea-to-air N$_2$O flux without a significant meridional transport (Suntharalingam and Sarmiento, 2000).

Elevated N$_2$O emission regions (> 50 mgN m$^{-2}$ yr$^{-1}$) are found in the Equatorial and Eastern Tropical Pacific, in the northern Indian ocean, in the northwestern Pacific, in the North Atlantic and in the Agulhas Current. In contrast, low fluxes (< 10 mgN m$^{-2}$ yr$^{-1}$) are simulated in the Southern Ocean, Atlantic and Pacific subtropical gyres and southern Indian Ocean. The large scale distribution of N$_2$O fluxes is coherent with Nevison et al. (2004) (Fig. 1c). This comes as a natural consequence of the relatively high contribution of nitrification and hence hotspots of N$_2$O emissions are associated with regions where higher export of organic matter occurs in the model.
There are however several discrepancies between the model and the data product. At high latitudes, the high N$_2$O emissions observed in the North Pacific are not well represented in our model, with a significant shift towards the western part of the Pacific basin, similar to other modeling studies (e.g., Goldstein et al., 2003; Jin and Gruber, 2003). The OMZ in the North Pacific, located at approximately 600m deep, is underestimated in the model due to the deficient representation of the Meridional Overturning Circulation (MOC) in the North Pacific in global ocean biogeochemical models, which in turn might suppress low oxygenated areas and therefore one potential N$_2$O source.

Discrepancies between model and observations also occur in the Southern Ocean, a region whose role in global N$_2$O fluxes remains debated due to the lack of observations and the occurrence of potential artifacts due to interpolation techniques reflected in data products such as that from Nevison et al., 2004. (e.g., Suntharalingam and Sarmiento, 2000, and Nevison et al, 2003). The model also overestimates N$_2$O emissions in the North Atlantic. The emphasis put on the nitrification pathway suggests that hotspots of carbon export are at the origin of elevated concentrations of N$_2$O in the subsurface. N$_2$O is quickly outgassed to the atmosphere, leading to such areas of high N$_2$O emissions in the model.

Model-data discrepancies can be seen as a function of latitude in Figure 1d. The modeled N$_2$O flux maxima peak at around 40°S, i.e., around 10° north to that estimated by Nevison et al. (2004), although Southern Ocean data must be interpreted with caution.

In the northern hemisphere the stripe in the North Pacific in not captured by the model, splitting the flux from the 45°N band into two peaks at 38°N and 55°N.

3.2 Contemporary N$_2$O concentrations and the relationship to O$_2$

The model results at present day were evaluated against the MEMENTO database (Bange et al., 2009), which contains about 25,000 measurements of co-located N$_2$O and dissolved O$_2$ concentrations. Table 1 summarizes the standard deviation and correlation coefficients for P.TEMP and P.OMZ compared to MEMENTO. The standard deviation of the model output is very similar to MEMENTO, i.e., around 16 nmol L$^{-1}$ of N$_2$O. However, the correlation coefficients between the sampled data points from MEMENTO and P.TEMP / P.OMZ are 0.49 and 0.42 respectively. Largest
discrepancies are found mostly in the deep ocean and in the OMZs.

Figure 2 compares the global average vertical profile of the observed N$_2$O against the results from the two parameterisations. The in-situ observations show three characteristic layers: the upper 100m layer with low (~10 nmol L$^{-1}$) N$_2$O concentration due to gas exchange keeping N$_2$O close to its saturation concentration, the mesopelagic layer, between 100 and 1500m, where N$_2$O is enriched via nitrification and denitrification in the OMZs, and the deep ocean beyond 1500m, with a relatively constant concentration of 18 nmol L$^{-1}$ on average. Both parameterizations underestimate the N$_2$O concentration in the upper 100 meters, where most of the N$_2$O is potentially outgassed to the atmosphere. In the second layer, P.OMZ shows a fairly good agreement with the observations in the 500 to 900m band, whereas P.TEMP is too low by ~10 nmol L$^{-1}$. Below 1500m, both parameterizations simulate too high N$_2$O compared to the observations. This may be caused by the lack or underestimation of a sink process in the deep ocean, or by the too high concentrations used to initialize the model, which persist due to the rather short spin-up time of only 150 yrs.

The analysis of the model simulated N$_2$O concentrations as a function of model simulated O$_2$ shows the differences between the two parameterizations more clearly (Fig. 3a and 3b). Such a plot allows us to assess the model performance with regard to N$_2$O (Jin and Gruber, 2003), without being subject to the strong potential biases introduced by the model’s deficiencies in simulating the distribution of O$_2$. This is particularly critical in the OMZs, where all models exhibit strong biases (Cocco et al., 2012; Bopp et al., 2013) (see also Fig. 3c). P.TEMP (Fig. 3a) slightly overestimates N$_2$O for dissolved O$_2$ concentrations above 100 µmol L$^{-1}$, and does not fully reproduce either the high N$_2$O values in the OMZs or the N$_2$O depletion when O$_2$ is almost completely consumed. P.OMZ (Figure 3b) overestimates the N$_2$O concentration over the whole range of O$_2$, with particularly high values of N$_2$O above 100 nmol L$^{-1}$ due to the exponential function used in the OMZs. There, the observations suggest concentrations below 80 nmol L$^{-1}$ for the same low O$_2$ values, consistent with the linear trend observed for higher O$_2$, which seems to govern over most of the O$_2$ spectrum, as suggested by Zamora et al. (2012). The discrepancy at low O$_2$ concentration may also stem from our choice of a too low N$_2$O consumption rate under essentially anoxic conditions. Finally, it should be considered that most of the MEMENTO data points are from OMZs and therefore N$_2$O
measurements could be biased towards higher values than the actual open ocean average, where our model performs better.

4. Future oceanic N$_2$O

4.1 N$_2$O sea-to-air flux

The global oceanic N$_2$O emissions decrease relatively little over the next century (Fig. 4a) between 4% and 12%. Namely, in P.TEMP, the emissions decrease by 0.15 Tg N yr$^{-1}$ from 3.71 TgN yr$^{-1}$ in 1985-2005 to 3.56 TgN yr$^{-1}$ in 2080-2100 and in P.OMZ, the decrease is slightly larger at 12%, i.e., amounting to 0.49 Tg N yr$^{-1}$ from 4.03 to 3.54 TgN yr$^{-1}$. Notable is also the presence of a negative trend in N$_2$O emissions over the 20$^{th}$ century, most pronounced in the P.OMZ parameterization. Considering the change over the 20$^{th}$ and 21$^{st}$ centuries together, the decreases increase to 7 and 15%.

These relatively small global decreases mask more substantial changes at the regional scale, with a mosaic of regions experiencing a substantial increase and regions experiencing a substantial decrease (Fig. 4b and 4c). In both parameterizations, the oceanic N$_2$O emissions decrease in the northern and south western oceanic basins (e.g., the North Atlantic and Arabian Sea), by up to 25 mg N m$^{-2}$ yr$^{-1}$. In contrast, the fluxes are simulated to increase in the Eastern Tropical Pacific and in the Bay of Bengal. For the Benguela Upwelling System (BUS) and the North Atlantic a bi-modal pattern emerges in 2100. As was the case for the present-day distribution of the N$_2$O fluxes, the overall similarity between the two parameterizations is a consequence of the dominance of the nitrification (high-O$_2$) pathway in both parameterizations.

Nevertheless there are two regions where more substantial differences between the two parameterizations emerge: the region overlying the oceanic OMZ at the BUS and the Southern Ocean. In particular, the P.TEMP parameterization projects a larger enhancement of the flux than P.OMZ at the BUS, whereas the emissions in the Southern Ocean are enhanced in the P.OMZ parameterization.

4.2 Drivers of changes in N$_2$O emissions
The changes in N\textsubscript{2}O emissions may stem from a change in net N\textsubscript{2}O production, a change in the transport of N\textsubscript{2}O from its location of production to the surface, or any combination of the two, which includes also changes in N\textsubscript{2}O storage. Next we determine the contribution of these mechanisms to the overall decrease in N\textsubscript{2}O emissions that our model simulated for the 21\textsuperscript{st} century.

4.2.1 Changes in N\textsubscript{2}O production

In both parameterizations, global N\textsubscript{2}O production is simulated to decrease over the 21\textsuperscript{st} century. The total N\textsubscript{2}O production in P.OMZ decreases by 0.41 TgN yr\textsuperscript{-1} in 2080-2100 compared to the mean value over 1985-2005 (Fig. 5a). The parameterization P.OMZ allows to isolate the contributions of high- and low-O\textsubscript{2} and will be analysed in greater detail in the following sections. N\textsubscript{2}O production via the high-O\textsubscript{2} pathway in P.OMZ decreases in the same order than total production, by 0.35 TgN yr\textsuperscript{-1} in 2080-2100 compared to present. The N\textsubscript{2}O production in the low-O\textsubscript{2} regions remains almost constant across the experiment. In P.TEMP parameterization, the reduction in N\textsubscript{2}O production is much weaker than in P.OMZ due to the effect of the increasing temperature. N\textsubscript{2}O production decreases by 0.07 TgN yr\textsuperscript{-1} in 2080-2100 compared to present (Fig. 5b).

The vast majority of the changes in the N\textsubscript{2}O production in the P.OMZ parameterization is caused by the high-O\textsubscript{2} pathway with virtually no contribution from the low-O\textsubscript{2} pathway (Fig. 5a). As the N\textsubscript{2}O production in P.OMZ parameterization is solely driven by changes in the O\textsubscript{2} consumption (Eq. (2)), which in our model is directly linked to export production, the dominance of this pathway implies that primary driver for the future changes in N\textsubscript{2}O production in our model is the decrease in export of organic matter (CEX). It was simulated to decrease by 0.97 PgC yr\textsuperscript{-1} in 2100, and the high degree of correspondence in the temporal evolution of export and N\textsubscript{2}O production in Fig. 5a confirms this conclusion.

The close connection between N\textsubscript{2}O production associated with the high-O\textsubscript{2} pathway and changes in export production is also seen spatially (Fig. 5c), where the spatial pattern of changes in export and changes in N\textsubscript{2}O production are extremely highly correlated (shown by stippling). Most of the small deviations are caused by lateral advection of organic
carbon, causing a spatial separation between changes in O$_2$ consumption and changes in organic matter export.

As there is an almost ubiquitous decrease of export in all of the major oceanic basins except at high latitudes, N$_2$O production decreases overall as well. Hotspots of reductions exceeding -10 mgN m$^{-2}$yr$^{-1}$ are found in the North Atlantic, the western Pacific and Indian basins (Fig. 5c). The fewer places where export increases, are also the locations of enhanced N$_2$O production. For example, a moderate increase of 3 mgN m$^{-2}$ yr$^{-1}$ is projected in the Southern Ocean, South Atlantic and Eastern Tropical Pacific. The general pattern of export changes, i.e., decreases in lower latitudes, increase in higher latitudes, is consistent generally with other model projection patterns (Bopp et al., 2013), although there exist very strong model-to-model differences at the more regional scale.

Although the global contribution of the changes in the low-O$_2$ N$_2$O production is small, this is the result of regionally compensating trends. In the model’s OMZs, i.e., in the Eastern Tropical Pacific and in the Bay of Bengal, a significant increase in N$_2$O production is simulated in these locations (Fig. 5d), with an increase of more than 15 mgN m$^{-2}$ yr$^{-1}$. This increase is primarily driven by the expansion of the OMZs in our model (shown by stippling), while changes in export contribute less. In effect, NEMO-PISCES projects a 20% increase in the hypoxic volume globally, from 10.2 to 12.3 x 10$^6$ km$^3$, and an increase in the suboxic volume from 1.1 to 1.6 x 10$^6$ km$^3$ in 2100 (Fig. 5e).

Elsewhere, the changes in the N$_2$O production through the low-O$_2$ pathway are dominated by the changes in export, thus following the pattern of the changes seen in the high-O$_2$ pathway. Overall these changes are negative, and happen to nearly completely compensate the increase in production in the OMZs, resulting in the near constant global N$_2$O production by the low-O$_2$ production pathway up to year 2100.

4.2.2 Changes in storage of N$_2$O

A steady increase in the N$_2$O inventory is observed from present to 2100. The pool of oceanic N$_2$O down to 1500m, i.e., potentially outgassed to the atmosphere, increases by 8.9 TgN from 1985-2005 to year 2100 in P.OMZ, whereas P.TEMP is less sensitive to changes with an increase of 4.0 TgN on the time period considered (Fig. 6a). The inventory in the upper 1500m in P.OMZ is 237.0 TgN at present, while in P.TEMP in
the same depth band is 179.8 TgN. This means that the projected changes in the inventory represent an increase of about 4% and 2% in P.OMZ and P.TEMP respectively.

This increase in storage of N$_2$O in the ocean interior shows an homogeneous pattern for P.TEMP, with particular hotspots in the North Pacific, North Atlantic and the eastern boundary currents in the Pacific (Fig. 6b). The spatial variability is more pronounced in P.OMZ (Fig. 6c), related in part to the enhanced production associated with OMZs. Most of the projected changes in storage are associated with shoaling of the mixed layer depth (shown by stippling), suggesting that increase in N$_2$O inventories is caused by increased ocean stratification. Enhanced ocean stratification, in turn, occurs in response to increasing sea surface temperatures associated with global warming (Sarmiento et al., 2004).

4.2.3 Effects of the combined mechanisms on N$_2$O emissions

The drivers of the future evolution of oceanic N$_2$O emissions emerge from the preceding analysis. Firstly, a decrease in the high-O$_2$ production pathway driven by a reduced organic matter remineralization reduces N$_2$O concentrations below the euphotic zone. Secondly, the increased N$_2$O inventory at depth is caused by increased stratification and therefore to a less efficient transport to the sea-to-air interface, leading to a less N$_2$O flux. The global changes in N$_2$O flux, N$_2$O production and N$_2$O storage for P.OMZ are presented in Fig. 7. Changes in N$_2$O flux and N$_2$O production are mostly of the same sign in almost all of the oceanic regions in line with the assumption of nitrification begin the dominant contribution to N$_2$O production. Changes in N$_2$O production in the subsurface are translated into corresponding changes in N$_2$O flux. There is only one oceanic region (Sub-Polar Pacific) where this correlation does not occur. N$_2$O inventory increases in all of the oceanic regions. The increase in inventory is particularly pronounced at low latitudes along the eastern boundary currents in the Equatorial and Tropical Pacific, Indian Ocean and also in smaller quantities in the Atlantic Ocean. Figure 7 shows how the decrease in N$_2$O production and increase in N$_2$O storage occurs in all oceanic basins.

The synergy among the driving mechanisms can be explored with a box model pursuing
two objectives. First, to separate the effect of physical (i.e., increased stratification) and
the biogeochemical (i.e., reduction of N₂O production in the high-O₂ regions)
mechanisms on N₂O emissions. In this way we can reproduce future projections
assuming that the only mechanisms ruling the N₂O dynamics in the future were those
that we have proposed in our hypothesis, i.e., increased stratification and reduction of
N₂O production in high-O₂ regions. Secondly, to explore a wider range of values for both
mixing (i.e., degree of stratification) and efficiency of N₂O production in high-O₂
conditions. In the particular NEMO-PISCES model projection we have studied, changes
in mixing and export are unique and can not be explored individually.
To this end, a box model was designed to explore the response of oceanic N₂O emissions
to changes in export of organic matter (hence N₂O production only in high-O₂
conditions) and changes in the mixing ratio between deep (> 100m) and surface (< 100m)
layers. We divided the water column into two compartments: a surface layer in the upper
100m where 80% of surface N₂O concentration is outgassed to the atmosphere (Eq. (3)),
and a deeper layer beyond 100m, where N₂O is produced from remineralization as a
fraction of the organic matter exported in the ocean interior (Eq. (4)). The N₂O
reservoirs in the surface and in the deep layer are allowed to exchange. The exchange is
regulated by a mixing coefficient ν:

\[
\begin{align*}
\text{surface } N_2O: & \quad \frac{dN_2O^s}{dt} = -\nu \cdot (N_2O^s - N_2O^d) - k \cdot N_2O^s \\
\text{deep } N_2O: & \quad \frac{dN_2O^d}{dt} = \nu \cdot (N_2O^s - N_2O^d) + \epsilon \cdot \Phi^{POC}
\end{align*}
\]

(3) (4)

where N₂O is N₂O in the surface, N₂Oᵈ is N₂O in the deep reservoir, \(\Phi^{POC}\) is the flux of
POC into the lower compartment, ν is the mixing coefficient between both
compartments, k is the fraction of N₂O outgassed to the atmosphere and e the fraction of
POC leading to N₂Oᵈ formation (Fig. S3 and Table S1, Supplementary Material).
Equations (3) and (4) are solved for a combination of POC fluxes and mixing coefficients,
reflecting the increasing stratification and the decrease in export production projected by
year 2100 (Sarmiento et al., 2004; Bopp et al., 2013).
A decrease in the N₂O flux is observed for a wide range of boundary conditions
simulating reduced mixing and export of POC (Fig. 8a). The most extreme scenario
explored with the box model suggests a -20% decrease in N₂O flux, although these
associated values of mixing and export are clearly unrealistic, from a nearly total
stagnation of ocean circulation between the deep and surface layers to an attenuation of
export of -20% in the global ocean.

The projected increase in $N_2O$ storage in the deep reservoir is reproduced by the box
model (Fig. 8b) at a wide range of changes particularly in mixing. Changes in mixing
dominate over changes in export as drivers of the increase in the $N_2O$ reservoir at depth.
A 25% decrease in mixing leads to an increase in storage similar to the one projected with
NEOM-PISCES (+10%), independently of changes in export of organic matter.

In general, the interplay between mixing and export of organic matter operates differently
when $N_2O$ flux or $N_2O$ inventory are considered. The box model experiment suggests
that the evolution of the $N_2O$ reservoir is driven almost entirely by changes in mixing,
while changes of mixing and export of organic matter have similar relevance when
modulating $N_2O$ emissions.

5. Caveats in estimating $N_2O$ using ocean biogeochemical models

The state variables upon which representation of $N_2O$ in models rely, i.e., oxygen and
export of carbon, are compared to the CMIP5 model ensemble to put our analysis in
context of the current state-of-the-art model capabilities. We focus here our analysis on
suboxic waters ($O_2 < 5 \mu mol \text{ L}^{-1}$) and on export production. Whereas CMIP5 models
tend to have large volumes of $O_2$ concentrations in the suboxic regime, it is not the case
for our NEOM-PISCES simulation, which clearly underestimates the volume of low-
oxygen waters as compared to the oxygen corrected World Ocean Atlas 2005
(WOA2005*) (Bianchi et al., 2012). The fact that NEOM-PISCES forced by IPSL-
CM5A-LR is highly oxygenated is confirmed by Figure 9, where the histogram of the full
$O_2$ spectrum of WOA2005* and NEOM-PISCES is shown. The $O_2$ distribution in the
model shows a deficient representation of the OMZs, with higher concentrations than
those from observations. The rest of the $O_2$ spectrum is well represented in our model.
The $O_2$ distribution in the model (Fig. 10) shows a deficient representation of the OMZs,
with higher concentrations than those from observations in WOA2005* and the other
CMIP5 models. NEOM-PISCES is therefore biased towards the high $O_2$ production
pathway of $N_2O$ due to the modeled $O_2$ fields.
When turning to the export of organic matter, NEMO-PISCES is close to the CMIP5 average value of 6.9 PgC yr\(^{-1}\). The overall distribution of export is also very similar to the CMIP5 model mean and both show smaller values than those from the data-based estimate of 9.84 PgC yr\(^{-1}\) from Dunne et al., 2007 (Fig. 10).

The uncertainties derived from present and future model projections can be estimated using the spread in the CMIP5 model projection of export of organic matter and assuming a linear response between nitrification (or export) and N\(_2\)O production in the subsurface, which is assumed to be quickly outgassed to the atmosphere. In NEMO-PISCES, a decrease in 13% in export leads to a maximum decrease in N\(_2\)O emissions of 12% in the P.OMZ scenario. Based on results by Bopp et al. (2013), changes in export of carbon span -7% to -18% in the CMIP5 model ensemble at the end of the 21st century and for RCP8.5. The spread would propagate to a similar range in projected N\(_2\)O emissions across the CMIP5 model ensemble. Applying these values to present N\(_2\)O emissions of 3.6 TgN yr\(^{-1}\), uncertainties are then bracketed between -0.25 and -0.65 TgN yr\(^{-1}\).

Regarding the low-\(O_2\) pathway, a similar approach is not that straightforward. Zamora et al., (2012) found that a linear relationship between AOU and N\(_2\)O production might occur even at the OMZ of the ETP. Zamora et al. (2012) acknowledged the fact that the MEMENTO database includes N\(_2\)O advected from other regions and that mixing could play a relevant role, smoothing the fit between N\(_2\)O and AOU from exponential to linear. However, Zamora et al. (2012) quoting Frame and Casciotti (2010), suggested that regions were an exponential relationship in N\(_2\)O production is present might be rare, that other non-exponential N\(_2\)O production processes might occur and therefore the plot they presented could describe the actual linear relationship between N\(_2\)O production and oxygen consumption. Based on this hypothesis, we could refer again to the linear relationship suggested in the high-\(O_2\) and export scenario. However, in this case the CMIP5 model projections of changes in the hypoxic and suboxic volumes differ substantially. Most models project an expansion of the OMZs in the +2% to +16% range in the suboxic volume (\(O_2 < 5 \mu\text{mol L}^{-1}\)). There are, however, models that project a slight reduction of 2%. Spatial variability of projections add to the spread between CMIP5 models. These discrepancies suggest that uncertainties from this spread must be interpreted with caution when estimating potential future N\(_2\)O emissions.
The use of O\textsubscript{2} consumption as a proxy for the actual N\textsubscript{2}O production plays therefore a pivotal role in the uncertainties in N\textsubscript{2}O model estimations. Future model development should aim at the implementation of mechanistic parameterizations of N\textsubscript{2}O production based on nitrification and denitrification rates. Further, in order to determine accurate O\textsubscript{2} boundaries for both N\textsubscript{2}O production and N\textsubscript{2}O consumption at the core of OMZs additional measurements and microbial experiments are needed. The contribution of the high-O\textsubscript{2} pathway that was considered in this model analysis might be a conservative estimate. Freing et al. (2012) suggested that the high-O\textsubscript{2} pathway could be responsible of 93% of the total N\textsubscript{2}O production. Assuming that changes in the N\textsubscript{2}O flux are mostly driven by N\textsubscript{2}O production via nitrification, that would suggest a larger reduction in the marine N\textsubscript{2}O emissions in the future. However, the mismatch between NEMO-PISCES and the Nevison et al. (2004) spatial distribution of N\textsubscript{2}O emissions in the western part of the basins suggests that changes in the future might not be as big as those projected in the model in such regions. Changes would be then distributed more homogeneously. The model assumption neglecting N\textsubscript{2}O production in the upper 100m avoids one important source of uncertainty in estimating global oceanic N\textsubscript{2}O fluxes. In case nitrification occurs in the euphotic layer, our results would be facing a significant uncertainty of at least ±25% in N\textsubscript{2}O emissions according to Zamora and Oschlies (2014) analysis using the UVic Earth System Climate Model. Finally, Zamora et al. (2012) observed a higher than expected N\textsubscript{2}O consumption at the core of the OMZ in the Eastern Tropical Pacific, occurring at an upper threshold of 10 µmol L\textsuperscript{-1}. The contribution of OMZs to total N\textsubscript{2}O production remains an open question. N\textsubscript{2}O formation associated with OMZs might be counterbalanced by its own local consumption, leading to the attenuation of the only increasing source of N\textsubscript{2}O attributable to the projected future expansion of OMZs (Steinacher et al., 2010; Bopp et al., 2013).

The combined effect of climate change and ocean acidification has not been analyzed in this study. N\textsubscript{2}O production processes might be altered by the response of nitrification to increasing levels of seawater pCO\textsubscript{2} (Huesemann et al., 2002; Beman et al. 2011). Beman et al. (2011) reported a reduction in nitrification in response to decreasing pH. This result suggests that N\textsubscript{2}O production might decrease beyond what we have estimated only due to climate change. Conversely, negative changes in the ballast effect could potentially...
reinforce nitrification at shallow depth in response to less efficient POC export to depth and shallow remineralization (Gehlen et al., 2011). Regarding N₂O formation via denitrification, changes in seawater pH as a consequence of higher levels of CO₂ might not be substantial enough to change the N₂O production efficiency, assuming a similar response of marine denitrifiers as reported for denitrifying bacteria have in terrestrial systems (Liu et al., 2010). Finally, the C:N ratio in export production (Riebesell et al., 2007) might increase in response to ocean acidification, potentially leading to a greater expansion of OMZs than simulated here (Oschlies et al., 2008; Tagliabue et al., 2011), and therefore to enhanced N₂O production associated with the low-O₂ pathway.

Changes in atmospheric nitrogen deposition have not been considered in this study. It has been suggested that due to anthropogenic activities the additional amount of reactive nitrogen in the ocean could fuel primary productivity and N₂O production. Estimates are however low, around 3-4% of the total oceanic emissions (Suntharalingam et al., 2012). Longer simulation periods could reveal additional effects on N₂O transport beyond changes in upwelling or meridional transport of N₂O in the subsurface (Suntharalingam and Sarmiento, 2000) that have been observed in this transient simulation. Long-term responses might include eventual ventilation of the N₂O reservoir in the Southern Ocean, highlighting the role of upwelling regions as an important source of N₂O when longer time periods are considered in model projections. Additional studies using other ocean biogeochemical models might also yield alternative values using the same parameterizations. N₂O production is particularly sensitive to the distribution and magnitude of export of organic matter and O₂ fields defined in models.

6. Contribution of future N₂O to climate feedbacks

Changes in the oceanic emissions of N₂O to the atmosphere will have an impact on atmospheric radiative forcing, with potential feedbacks on the climate system. Based on the estimated 4 to 12% decrease in N₂O sea-to-air flux over the 21st century under RCP8.5, we estimated the feedback factor for these changes as defined by Xu-Ri et al. (2012). Considering the reference value of the pre-industrial atmospheric N₂O concentration of 280 ppb in equilibrium, and its associated global N₂O emissions of 11.8 TgN yr⁻¹, we quantify the resulting changes in N₂O concentration per degree for the two
projected emissions in 2100 using P.TEMP and P.OMZ. The model projects changes in
N$_2$O emissions of -0.16 and -0.48 TgN yr$^{-1}$ respectively, whereas surface temperature is
assumed to increase globally by 3°C on average according to the physical forcing used in
our simulations. These results yield -0.05 and -0.16 TgN yr$^{-1}$ K$^{-1}$, or alternatively -1.25
and -3.80 ppb K$^{-1}$ for P.TEMP and P.OMZ respectively. Using Joos et al. (2001) we
calculate the feedback factor in equilibrium for projected changes in emissions to be -
0.005 and -0.014 W m$^{-2}$K$^{-1}$ in P.TEMP and P.OMZ.
Stocker et al. (2013) projected changes in terrestrial N$_2$O emissions in 2100 using
transient model simulations leading to feedback strengths between +0.001 and +0.015 W
m$^{-2}$K$^{-1}$. Feedback strengths associated with the projected decrease of oceanic N$_2$O
emissions are of the same order of magnitude as those attributable to changes in the
terrestrial sources of N$_2$O, yet opposite in sign, suggesting a compensation of changes in
radiative forcing due to future increasing terrestrial N$_2$O emissions. At this stage,
potential compensation between land and ocean emissions is to be taken with caution, as
it relies of a single model run with constant atmospheric N$_2$O.

7. Conclusions

Our simulations suggest that anthropogenic climate change could lead to a global
decrease in oceanic N$_2$O emissions during the 21$^{st}$ century. This maximum projected
decrease of 12% in marine N$_2$O emissions for the business-as-usual high CO$_2$ emissions
scenario would compensate for the estimated increase in N$_2$O fluxes from the terrestrial
biosphere in response to anthropogenic climate change (Stocker et al. 2013), so that the
climate-N$_2$O feedback may be more or less neutral over the coming decades.
The main mechanisms contributing to the reduction of marine N$_2$O emissions are a
decrease in N$_2$O production in high oxygenated waters as well as an increase in ocean
vertical stratification that acts to decrease the transport of N$_2$O from the sub-surface to
the surface ocean. Despite the decrease in both N$_2$O production and N$_2$O emissions,
simulations suggest that the global marine N$_2$O inventory may increase from 2005 to
2100. This increase is explained by the reduced transport of N$_2$O from the production
zones to the air-sea interface.
Differences between the two parameterizations used here are more related to
biogeochemistry rather than changes in ocean circulation. Despite sharing the high-O$_2$
N$_2$O production pathway, leading to a decrease in N$_2$O emissions in both cases, the role
of warming in P.TEMP or higher N$_2$O yields at low-O$_2$ concentrations in P.OMZ translate into notable differences in the evolution of the two production pathways. However, the dominant effect of changes in stratification in both parameterizations drives ultimately the homogeneous response of the parameterizations considered in model projections in the next century.

The N$_2$O production pathways demand however a better understanding in order to enable an improved representation of processes in models. At a first order, the efficiencies of the production processes in response to higher temperatures or increased seawater pCO$_2$ are required. Second order effects such as changes in the O$_2$ boundaries at which nitrification and denitrification occur must be also taken into account. In the absence of process-based parameterizations, N$_2$O production parameterizations will still rely on export of organic carbon and oxygen levels. Both need to be improved in global biogeochemical models.

The same combination of mechanisms (i.e., change in export production and ocean stratification) have been identified as drivers of changes in oceanic N$_2$O emissions during the Younger Dryas by Goldstein et al. (2003). The N$_2$O flux decreased, while the N$_2$O reservoir was fueled by longer residence times of N$_2$O caused by increased stratification. Other studies point towards changes in the N$_2$O production at the OMZs as the main reason for variations in N$_2$O observed in the past (Suthhof et al., 2001). Whether these mechanisms are plausible drivers of changes beyond year 2100 remains an open question that needs to be addressed with longer simulations.
8. Acknowledgements

We thank Cynthia Nevison for providing us the N₂O sea-to-air flux dataset. We thank Annette Kock and Herman Bange for the availability of the MEMENTO database (https://memento.geomar.de). We thank Christian Ethé for help analyzing PISCES model drift. Comments by Parvadha Suntharalingam and three anonymous reviewers improved significantly this manuscript. Nicolas Gruber acknowledges the support of ETH Zürich. This work has been supported by the European Union via the Greencycles II FP7-PEOPLE-ITN-2008, number 238366.

(2004) and (d) latitudinal \( \text{N}_2\text{O} \) sea-to-air flux (in \( \text{TgN deg}^{-1} \text{ yr}^{-1} \)) from Nevison et al. (2004) (black), P.TEMP (blue) and P.OMZ (red).
Fig. 2: Global average depth profile of N$_2$O concentration (in nmol L$^{-1}$) from the MEMENTO database (dots) (Bange et al., 2009), P.TEMP (blue) and P.OMZ (red). Model parameterizations are averaged over the 1985 to 2005 time period from the historical simulation.
Fig. 3: Relationship between O$_2$ concentration (in µmol L$^{-1}$) and N$_2$O concentration (in nmol L$^{-1}$) in the MEMENTO database (black) (Bange et al., 2009), compared to model (a) P.TEMP (blue) and (b) P.OMZ (red) parameterizations averaged over the 1985 to 2005 time period from the historical simulation.
Fig 4: (a) N$_2$O sea-to-air flux (in TgN yr$^{-1}$) from 1851 to 2100 in P.TEMP (blue) and P.OMZ (red) using the historical and future RCP8.5 simulations. Dashed lines indicate the mean value over the 1985 to 2005 time period. Change in N$_2$O sea-to-air flux (mgN m$^{-2}$ yr$^{-1}$) from the averaged 2080-2100 to 1985-2005 time periods in future RCP8.5 and historical simulations in (b) P.TEMP and (c) P.OMZ parameterizations.
Fig 5: (a) Anomalies in export of organic matter at 100m (green), low-O₂ production pathway (short dashed red), high-O₂ production pathway (long dashed red) and total P.OMZ production (red) from 1851 to 2100 using the historical and future RCP8.5 simulations. (b) Anomalies in export of organic matter at 100m (green) and P.TEMP production (blue) over the same time period. (c) Change in high-O₂ production pathway of N₂O (in mgN m⁻² yr⁻¹) in the upper 1500m between 2080-2100 to 1985-2005 averaged time periods. Hatched areas indicate regions where change in export of organic matter at 100m deep have the same sign as in changes in high-O₂ production pathway. (d) Change in low-O₂ production pathway of N₂O (in mgN m⁻² yr⁻¹) in the upper 1500m between 2080-2100 to 1985-2005 averaged time periods. Hatched areas indicate regions where oxygen minimum zones (O₂ < 5 µmol L⁻¹) expand. (e) Volume (in 10⁶ km³) of hypoxic (black, O₂ < 60 µmol L⁻¹) and suboxic (red, O₂ < 5 µmol L⁻¹) areas in the 1851 to 2100 period in NEMO-PISCES historical and future RCP8.5 simulations.
Fig 6: (a) Anomalies in N₂O inventory (in TgN) from 1851 to 2100 in P.TEMP (blue) and P.OMZ (red) using the historical and future RCP8.5 simulations in the upper 1500m. Change in vertically integrated N₂O concentration (in mgN m⁻³) in the upper 1500m using NEMO-PISCES model mean from the averaged 2080-2100 to 1985-2005 time periods in future RCP8.5 and historical scenarios respectively in (b) P.TEMP and (c) P.OMZ. Hatched areas indicate regions where the annual mean mixed layer depth is reduced by more than 5m in 2080-2100 compared to 1985-2005.

Fig. 7: Change in the whole water column in $N_2O$ sea-to-air flux (blue), high-$O_2$ production pathway (red), low-$O_2$ production pathway (orange), total $N_2O$ production (yellow) and $N_2O$ inventory (green) for P.OMZ from the averaged 2080-2100 to present 1985-2005 averaged time period in the NEMO-PISCES historical and future RCP8.5 simulations (based on Mikaloff-Fletcher et al. (2006) oceanic regions).
Fig. 8: Box model results, analyzing the effect of changes in ocean circulation by reducing the mixing coefficient (μ in %) and changes in biogeochemistry by reducing export of organic matter (in %) separately in N₂O sea-to-air emissions and N₂O inventory in 2100. (a) Constant regimes in percentage of the historical N₂O sea-to-air flux: 95% pink, 90% blue, 85% cyan and 80% green, and (b) Constant regimes in percentage of the historical N₂O concentration in the deep: 90% pink, 110% blue, 125% cyan and 150% green.
Figure 9: Distribution of $O_2$ concentration in NEMO-PISCES 1985 to 2005 averaged time period (black) compared to the oxygen-corrected World Ocean Atlas (red) from Bianchi et al. (2012). Interval widths are $O_2$ concentrations at steps of 5 µmol L$^{-1}$. 

[Diagram showing the distribution of $O_2$ concentrations with data points and intervals]
Figure 10: Averaged $O_2$ concentration between 200-600m depth (in µmol L$^{-1}$) (left) and export of carbon (in mmolC m$^{-2}$ d$^{-1}$) (right) in (a) WOA2005* and Dunne et al. (2007), (b) CMIP5 model mean historical simulations over the 1985-2005 time period and (c) NEMO-PISCES for the present 1985-2005 time period.

The $O_2$ modulation function $f(O_2)$ in P.OMZ is defined as,

$$f(O_2) = \begin{cases} \frac{O_2}{O_2^*} & 0 < O_2 < O_2^* \\ 1 & O_2^* < O_2 < O_2^* \\ 0.7 \cdot \exp -0.5(O_2 - O_2^*2)/O_2^*2 + 0.3 \cdot \exp -0.05(O_2 - O_2^*2)/O_2^*2 & O_2 \geq O_2^* \end{cases}$$

where $O_2^*$ is 1 µmol L$^{-1}$ and $O_2^*$ is 5 µmol L$^{-1}$. The shape of the function is shown in Fig. S1.

Fig. S1: Oxygen modulating function $f(O_2)$ in the low-$O_2$ production pathway term included in P.OMZ from Goreau et al. (1980).
Fig. S2: Vertically integrated (a) high-$\text{O}_2$ and (b) low-$\text{O}_2$ production pathways (in gN m$^{-2}$ yr$^{-1}$) in P.OMZ for the averaged 1985 to 2005 historical simulation.
Fig. S3: Diagram of the box model. N₂O inventory is separated into surface and deep concentrations above and below 100m. The fraction of N₂O outgassed to the atmosphere ($k$), mixing ratio ($\nu$) between deep and surface and the rate of N₂O production from the export of organic matter to depth ($e$) regulate the N₂O budget in the ocean interior.
