We thank the anonymous referee #3 for the careful reading of the revised manuscript. All of the Reviewer’s suggestions have been taken into account and the resulting modifications appear in a revised version of the manuscript at the end of this response. R3-Cx : Referee comment, R3-Rx: authors response

The authors have done a thorough job in addressing the reviewers’ concerns and producing a revised manuscript. There are only two significant outstanding issues that should be easily rectified together with a few minor points.

We thank the Reviewer #3 for acknowledging the modifications made to our revised paper. We have addressed the two remaining issues (strong flux attenuation and location of resting spore formation) in the revised version of the paper.

**STRONG FLUX ATTENUATION considerations**

R3-C1: Although the companion manuscript was revised, there remained too strong an emphasis on the case for flux attenuation. Accordingly the authors were requested to reduce emphasis on this. There are a couple of points in the text of the present manuscript where the emphasis needs to change somewhat to be consistent with this.

Line 114 delete the words “an intense”

R3-R1: change made.

R3-C2: In the Discussion: “4.1 The significance of resting spores for POC flux” Lines 587 starting “In a companion paper....” to line 593 should be deleted.

R3-R2: change made.

R3-C3: Elsewhere in the Discussion (line 621) the Santa Barbara example fits more with the “coastal influenced regions” category leaving the Treppke (1996) and Rynearson (2013) examples as open ocean occurrences.

R3-R3: We placed the Santa Barbara example into the coastal influenced regions examples.

MS change lines 566 – 573: “Numerous sediment trap studies have reported a strong contribution, if not dominance, of CRS to diatom fluxes at depth in various oceanographic regions: firstly, in coastal influenced regions (e.g. Antarctic Peninsula (Leventer, 1991), Bransfield Strait (Abelmann and Gersonde, 1991), Gulf of California (Sancetta, 1995), the Omura Bay (Kato et al., 2003), Santa Barbara basin (Lange, 1997), North Pacific Ocean (Chang et al., 2013) and the Artic (Onodera et al., 2014)), secondly in upwelling-influenced regions (Eastern Equatorial Atlantic (Treppke et al., 1996)) and finally in the open ocean in the subarctic Atlantic (Rynearson et al., 2013).”
LOCATION OF RESTING FORMATION

R3-C3: In the companion paper, attention was drawn to the possible decoupling of the observed satellite chlorophyll surface peaks with one month time difference between these and resting spore flux (Figure 1 of the present manuscript). In fact, in the North Atlantic example referenced (Rynearson et al. 2013), the resting spores found dominating the traps were a very small component of surface samples, leading to the suggestion of resting spore formation at some depths in the water column. Mention should be made of a similar possible subsurface location for spore production off Kerguelen. This would explain the apparent temporal miss-match. This is an important point, since it emphasizes the need for more study of the full range of the surface ocean. Not just that detectable by satellite.

R3-R3: We have included this hypothesis in the section dedicated to the discussion of the triggering factors of resting spore formation.

MS change lines 603 – 618: “Nutrient depletion has been shown to trigger resting spore formation in Chaetoceros Hyalochaete laboratory cultures (Garrison, 1981; Sanders and Cibik, 1985; Kuwata et al., 1993; Oku and Kamatani, 1997) over relatively rapid timescales (6 to 48 h, McQuoid and Hobson, 1996). Although Si(OH)₄ depletion appears to be the most likely biogeochemical trigger at the Kerguelen Plateau (from 24 µmol L⁻¹ in early spring to 2 µmol L⁻¹ in summer, (Mosseri et al., 2008; Closset et al., 2014)), other environmental factors (iron or light availability) could influence resting spore formation. Notably, dissolved iron concentration in the mixed layer rapidly decreases to 0.1~0.2 nmol L⁻¹ after the beginning of the spring bloom at A3, however the vertical entrainment is much weaker in summer compared to spring (Bowie et al., 2014). Rynearson et al. (2013) reported the absence of spores in the mixed layer despite a strict dominance into the trap samples. A resting spore formation at some depth (possibly implying a light control) would explain the temporal decoupling between the surface production tracked by the satellite in the surface layer (first ~20 meters) and the export events. Further work to establish seasonal dynamics of factors linked to diatom life cycles and specifically the formation of resting spore is necessary.”

MINOR POINTS.

Line 2: it would be more informative to specify “diatom resting spores” in the title – insert “resting”
Change made.

Line 3: should be pellets (plural) in title
Change made.

Line 248: should be “with the exception of”
Change made.

Lines 846 – 847: add “of” to read “particles exported out of the mixed layer”
Change made.

Line 892: should read “This might result..” (delete s)
Change made.

REFERENCES.

Something seems to have gone wrong with Endnote: the Grigorov et al 2014a and 2014b are actually the same paper (Lines 1144 - 1149).

Abstract

The biological composition of the material exported to a moored sediment trap located under the winter mixed layer of the naturally-fertilized Kerguelen Plateau in the Southern Ocean was studied over an annual cycle. Despite iron availability in spring, the annual particulate organic carbon (POC) export (98.2 mmol m\textsuperscript{-2}) at 289 m was low but annual biogenic silica export was significant (114 mmol m\textsuperscript{-2}). This feature was related to the abundance of empty diatom cells and the ratio of full:empty cells exerted a first order control in BSi:POC export stoichiometry of the biological pump. Chaetoceros Hyalochaete spp. and Thalassiosira antarctica resting spores were responsible for more than 60 % of the annual POC flux that occurred during two very short export events of <14 days in spring-summer. Relatively low diatom fluxes were observed over the remainder of the year. Faecal pellet contribution to annual carbon flux was low (34 %) and reached its seasonal maximum in
The seasonal progression of faecal pellet types revealed a clear transition from small spherical shapes (small copepods) in spring, larger cylindrical and ellipsoid shapes in summer (euphausiids and large copepods) and finally large tabular shapes (salps) in autumn and winter. We propose in this High Biomass, Low Export (HBLE) environment that small, but highly silicified, and fast-sinking resting spores are able to bypass the intense grazing pressure and efficient carbon transfer to higher trophic levels that are responsible for the low fluxes observed during the remainder of the year. More generally, our study also provides a statistical framework linking the ecological succession of diatom and zooplankton communities to the seasonality of carbon and silicon export within an iron-fertilized bloom region in the Southern Ocean.
1 Introduction

The Southern Ocean is the place of exposure of old upwelled waters to the atmosphere and the formation of mode waters, thereby ventilating an important part of the global Ocean and playing a central role in distributing heat, carbon and nutrients in the global Ocean (Sarmiento et al., 2004; Takahashi et al., 2012; Sallée et al., 2012). Silicon trapping occurs in the Southern Ocean because silicon is stripped out of the euphotic zone more efficiently than phosphorous and nitrogen (Holzer et al., 2014). It is generally acknowledged that regional variations in plankton community structure are responsible for variations in nutrient stoichiometry in the Southern Ocean (Jin et al., 2006; Weber and Deutsch, 2010) and that the biological pump is a central process regulating this stoichiometry (Ragueneau et al., 2006; Salter et al., 2012; Primeau et al., 2013). These characteristics emphasize the importance of biological processes in the Southern Ocean waters for the availability of silicic acid and nitrate (Sarmiento et al., 2004; Dutkiewicz et al., 2005) as well as phosphate (Primeau et al., 2013) at lower latitudes, thereby regulating part of the productivity of the global Ocean. It has been proposed that change in the uptake ratio of silicate and nitrate by Southern Ocean phytoplankton in response to increased iron availability during the Last Glacial Maximum could have played a substantial role in varying atmospheric CO₂ (Brzezinski et al., 2002; Matsumoto et al., 2002).

Primary production in the Southern Ocean is regulated by macro- and micronutrient availability (Martin et al., 1990; Moore et al., 2001; Nelson et al., 2001; Moore et al., 2013) and light-mixing regime (Venables and Moore, 2010; Blain et al., 2013). The complex interaction of these factors introduces strong spatial heterogeneity in the distribution of primary producer biomass (Arrigo et al., 1998; Thomalla et al., 2011). In particular, High Nutrient, Low Chlorophyll (HNLC) areas in the open ocean contrast strongly with highly productive, naturally fertilized, blooms located downstream of island systems such as the
Keguelen Plateau (Blain et al., 2001, 2007), Crozet Islands (Pollard et al., 2002) and South Georgia (Park et al., 2010; Tarling et al., 2012). The diatom-dominated phytoplankton blooms characteristic of these island systems are the product of multiple environmental conditions favorable for their rapid growth (Quéguiner, 2013), which appear to promote POC export from the mixed layer (Nelson et al., 1995; Buesseler, 1998). However the ecological traits of certain species can impact the BSi:POC export stoichiometry (Crawford, 1995; Salter et al., 2012), and may therefore control the biogeochemical function of a particular region of the Southern Ocean (Smetacek et al., 2004; Assmy et al., 2013).

Among the numerous ecological characteristics of plankton communities, algal aggregation (Jackson et al., 2005; Burd and Jackson, 2009), mesozooplankton faecal pellets (Lampitt et al., 1990; Wilson et al., 2008, 2013), vertical migrations of zooplankton and mesopelagic fish (Jackson and Burd, 2001; Steinberg et al., 2002; Davison et al., 2013), radiolarian faecal pellets (Lampitt et al., 2009), and diatom resting spore formation, (Salter et al., 2012; Rynearson et al., 2013) have all been highlighted as efficient vectors of carbon export out of the surface mixed layer. The challenge in describing the principal ecological processes regulating POC export fluxes is the requirement to have direct access to sinking particles. Many of the processes described occur in the upper layers of the ocean, where circulation can strongly influence the reliability of sediment trap collections (Baker et al., 1988; Buesseler et al., 2007). Short term deployments of free drifting sediment traps can be an efficient solution to minimize the hydrodynamic bias (Buesseler et al., 2000; Lampitt et al., 2008) but spatial and temporal decoupling of production and export needs to be considered (Salter et al., 2007; Rynearson et al., 2013). In regions characterized by relatively weak circulation, moored sediment trap observations in areas of naturally fertilized production can track temporal succession of exported material from long-term (several month) blooms (Westberry et al., 2013). Such an approach can partially resolve how ecological processes in
plankton communities regulate POC and biomineral export out of the mixed layer (Salter et al., 2012; Salter et al., 2014), although selective processes during export may modify original surface features

The central Kerguelen Plateau is a good environment to study the ecological vectors of export with sediment traps due to the naturally fertilized recurrent bloom (Blain et al., 2007) and shallow bathymetry that breaks the strong Antarctic Circumpolar Current flow (Park et al., 2008, 2014). As reported in the companion paper (Rembauville et al., 2014), annual POC export measured by the sediment trap deployment at 289 m beneath the southeastern iron-fertilized Kerguelen bloom is 98±4 mmol m\(^{-2}\) y\(^{-1}\). This downward flux of carbon may account for as little as ~1.5% of seasonal net community carbon production (6.6±2.2 mol m\(^{-2}\), Jouandet et al., 2008) and <2% of seasonally-integrated POC export estimated at 200 m from a dissolved inorganic carbon budget (5.1 molC m\(^{-2}\), Blain et al., 2007). Although hydrodynamical and biological biases related to the shallow moored sediment trap deployment may partly explain the low POC fluxes we report, independent measurements of low POC fluxes (>300 m) at the same station (Ebersbach and Trull, 2008; Jouandet et al., 2014) are consistent with the hypothesis of an intense flux attenuation below the winter mixed layer. These observations suggest a ‘High Biomass, Low Export’ (HBLE, Lam and Bishop, 2007) status characterizing the productive Kerguelen Plateau. HBLE status appears to be a common feature of other productive sites of the Southern Ocean (Lam and Bishop, 2007; Ebersbach et al., 2011; Lam et al., 2011; Maiti et al., 2013; Cavan et al., 2015). Describing the temporal succession of POC and BSi flux vectors from the Kerguelen Plateau is of interest to increase our understanding of the ecological processes characterizing HBLE environments.

Numerous studies have described diatom fluxes from sediment trap records in the Southern Ocean (Leventer and Dunbar, 1987; Fischer et al., 1988; Abelmann and Gersonde, 1991; Leventer, 1991; Gersonde and Zielinski, 2000; Fischer et al., 2002; Pilskaln et al.,
2004; Ichinomiya et al., 2008; Salter et al., 2012). Highest diatom fluxes recorded by sediment traps (>10^9 valves m^-2 d^-1) were observed in the Seasonal Ice Zone (SIZ) near Prydz Bay and Adélie Land and were dominated by *Fragilariopsis kerguelensis* and smaller *Fragilariopsis* species such as *Fragilariopsis curta* and *Fragilariopsis cylindrus* (Suzuki et al., 2001; Pilskaln et al., 2004). These high fluxes occurred in summer and were associated with the melting of sea ice. Changes in light availability and melt water input appear to establish favorable conditions for the production and export of phytoplankton cells (Romero and Armand, 2010). In the Permanently Open Ocean Zone (POOZ), highest diatom fluxes recorded were two orders of magnitude lower ~10^7 valves m^-2 d^-1 (Abelmann and Gersonde, 1991; Salter et al., 2012; Grigorov et al., 2014) and typically represented by *F. kerguelensis* and *Thalassionema nitzschioides*. One notable exception is the naturally iron-fertilized waters downstream of the Crozet Plateau where resting spores of *Eucampia antarctica* var. *antarctica* dominated the diatom export assemblage (Salter et al., 2012).

Other studies have reported faecal pellet contribution to POC fluxes in the Southern Ocean (Dunbar, 1984; Wefer et al., 1988; Wefer et al., 1990; Wefer and Fisher, 1991; Dubischar and Bathmann, 2002; Suzuki et al., 2001,2003; Accornero and Gowing, 2003; Schnack-Schiel and Isla, 2005; Gleiber et al., 2012) with a particular emphasis on shelf environments where faecal pellet contribution to POC flux was typically higher than in the oceanic regions (Wefer et al., 1990; Wefer and Fischer, 1991; Schnack-Schiel and Isla, 2005). In the Ross Sea, a northward decreasing contribution to carbon flux of 59 %, 38 % and 15 % for southern, central and northern areas was reported from 235 m sediment traps deployments (Schnack-Schiel and Isla, 2005). Faecal pellets in the Ross Sea were generally represented by larger shapes with only 2 to 3 % of them present as small spherical or ellipsoid shapes and total faecal pellet flux was slightly higher than 10^3 pellet m^-2 d^-1. High faecal pellet contribution to carbon fluxes (> 90 %) have been observed in the Bransfield Strait and the
Marginal Ice Zone of the Scotia Sea, and have been linked to the abundance of the Antarctic krill *Euphausia superba*, resulting in maximum recorded fluxes of $>5 \times 10^5$ pellets m$^{-2}$ d$^{-1}$ (Bodungen, 1986; von Bodungen et al., 1987; Wefer et al., 1988). The strong contribution of krill faecal pellets to carbon flux in the western Antarctic Peninsula was confirmed over several years of observations, with the highest contributions to carbon flux succeeding the phytoplankton bloom in January and February (Gleiber et al., 2012).

In the present study, particulate material exported from the mixed layer in the naturally fertilized Permanently Open Ocean Zone (POOZ) of the Kerguelen Plateau is described from an annual sediment trap mooring. To develop our understanding of seasonal variability in the ecological flux vectors and particle biogeochemistry we investigate the link between the chemical (POC, PON, BSi) and biological (diatom species and faecal pellet types) components of exported particles. Furthermore, we advance the limitations of previous studies by explicitly distinguishing full and empty diatom cells in the exported material and thereby determine species-specific roles for carbon and silica export.

2 Materials and methods

As part of the multidisciplinary research program KEOPS2 a moored sediment trap (Technicap PPS3) was deployed at 289 m (seafloor depth: 527 m) at the representative bloom station A3 (50°38.3’ S – 72°02.6’ E) for a period of 321 days (21 October 2011 to 7 September 2012). The sediment trap mooring was located within an iron-fertilized bloom site on the southern part of the Kerguelen Plateau (Blain et al., 2007). The cup rotation dates of the sediment trap are listed in Table 1. Details of sediment trap design, hydrological conditions, sample processing, POC and PON analyses and surface chlorophyll $a$ data extraction are described in a companion paper (Rembauville et al., 2014). Comparison with thorium-based estimates of carbon export suggests a trapping efficiency of 15-30 % relative to
the proxy, although strong particle flux attenuation between 200 m and the trap depth (289 m) might also contribute to the low fluxes. We therefore interpret our results to accurately reflect the relationships between the biological and geochemical signals of the material caught by the sediment trap, which we acknowledge may not necessarily represent the entire particle export at 289 m.

2.1 Biogenic and lithogenic silicon analyses

For the analysis of biogenic silica (BSi) and lithogenic silica (LSi), 2 to 8 mg of freeze-dried material were weighed (Sartorius precision balance, precision 10⁻⁴ g) and placed into falcon tubes. The extraction of silicon from biogenic and lithogenic particle phases was performed following the Ragueneau et al. (2005) triple NaOH/HF extraction procedure. Silicic acid (Si(OH)₄) resulting from NaOH extractions was measured automatically on a Skalar 5100 autoanalyzer whereas Si(OH)₄ resulting from HF extraction was measured manually on a Milton Roy Spectronic 401 spectrophotometer. Si(OH)₄ analyses were performed colorimetrically following Aminot and Kerouel (2007). Standards for the analysis of samples from the HF extraction were prepared in an HF/H₃BO₄ matrix, ensuring the use of an appropriate calibration factor that differs from Milli-Q water. The contribution of LSi to the first leaching was determined by using Si:Al ratios from a second leaching step (Ragueneau et al., 2005). Aluminum concentrations were measured by spectrophotometry (Howard et al., 1986). The triple extraction procedure is optimized for samples with a BSi content < 10 µmol. For some samples (cup #3, #4, #6, #7, #8, #9 and #10) the Si:Al molar ratio in the second leachate was high (>10) indicating the incomplete dissolution of BSi. For these samples it was not possible to use Si:Al ratios to correct for LSi leaching. A crustal Si:Al mass ratio of 3.74 (Taylor and McLennan, 1986) was therefore used and applied to all the samples for consistency. Precision (estimated from measurement of 25 independent samples) was 13 nmol/mg, which represents <1 % of the BSi content in all samples and 14 % of the mean LSi
Blank triplicates from each extraction were below the detection limit. BSi results from this method were compared to the kinetic method from DeMaster (1981). There was an excellent agreement between the two methods (Spearman rank correlation, n = 12, p < 0.001, $\text{BSi}_{\text{kinetic}} = 1.03 \times \text{BSi}_{\text{triple extraction}} - 0.08$, data not shown). To estimate the contribution of opal to total mass flux, we assumed an opal composition of SiO$_2$·0.4H$_2$O (Mortlock and Froelich, 1989).

In order to correct for the dissolution of BSi during deployment and storage, Si(OH)$_4$ excess was analyzed in the overlying preservative solution. Particulate BSi fluxes were corrected for dissolution assuming that excess silicic acid originated only from the dissolution of BSi phases. Si(OH)$_4$ excess was always <10% of total (dissolved + particulate) Si concentrations. Error propagation for POC, PON, BSi fluxes and molar ratios were calculated as the quadratic sum of the relative error from triplicate measurements of each variable.

### 2.2 Diatom identification, fluxes and biomass

Many sediment trap studies reporting diatom fluxes in the Southern Ocean use a micropaleontological protocol that oxidizes organic material (KMnO$_4$, HCl, H$_2$O$_2$) thereby facilitating the observation of diatom valves (see Romero et al., 1999, 2000 for a description). In the present manuscript, our specific aim was to separately enumerate full and empty diatom cells captured by the sediment trap to identify key carbon or silicon exporters amongst the diatom species. We therefore used a biological method following a similar protocol to that of (Salter et al., 2007, 2012). To prepare samples for counting, 2 mL of a gently homogenized 1/8 wet aliquot were diluted in a total volume of 20 mL of artificial seawater (S = 34). In order to minimize the exclusion and/or breaking of large or elongated diatom frustules (e.g. Thalassiothrix antarctica), the pipette tip used for sub-sampling was modified to increase the tip aperture to >2 mm. The diluted and homogenized sample was placed in a Sedgewick-Rafter counting chamber (Pyser SGE S52, 1 mL chamber volume). Each sample was
observed under an inverted microscope (Olympus IX71) with phase contrast at 200x and 400x magnification. Diatom enumeration and identification was made from one quarter to one half of the counting chamber (depending on cell abundance). The total number of diatoms counted was >400 in all the cups with the exception of the winter cup #12 (May – September 2012) where the diatom abundance was low (<100 diatoms counted). Diatoms species were identified following the recommendations of Hasle and Syvertsen (1997). All whole, intact and recognizable frustules were enumerated. Full and empty cells were counted separately, following suggestions in Assmy et al. (2013).

Due to the lower magnification used and preserved cell contents sometimes obscuring taxonomic features on the valve face, taxonomic identification to the species level was occasionally difficult and necessitated the categorizing of diatom species to genus or taxa groupings in the following manner: Chaetoceros species of the subgenus Hyalochaete resting spores (CRS) were not differentiated into species or morphotypes but were counted separately from the vegetative cells; Fragilariopsis separanda and Fragilarsiopsis rhombica were grouped as Fragilariopsis separanda/rhombica; Membraneis imposter and Membraneis challengeri and species of the genera Banquisia and Manguinea were denominated as Membraneis spp. (Armand et al., 2008a); diatoms of the genus Haslea and Pleurosigma were grouped as Pleurosigma spp.; all Pseudo-nitzschia species encountered were grouped as Pseudo-nitzschia spp.; Rhizosolenia antennata and Rhizosolenia styliformis were grouped as Rhizosolenia antennata/styliformis; large and rare Thalassiosira oliverana and Thalassiosira tumida were grouped as Thalassiosira spp.; Thalassiosira antarctica resting spores (TRS) were identified separately from the vegetative cells; small centric diatoms (<20 µm) represented by Thalassiosira gracilis and other Thalassiosira species were designated as Small centrics (< 20µm); and finally large and rare centrics including Azpetitia tabularis, Coscinodiscus spp. and Actinocyclus curvatulus were grouped as Large centrics (>20 µm).
Full and empty frustules of each species or taxa grouping were distinguished and enumerated separately. The cell flux for each diatom species or taxa grouping was calculated according to Equation (1):

\[
Cell\ flux = N_{\text{diat}} \times d \times 8 \times V_{\text{cup}} \times \frac{1}{0.125} \times \frac{1}{\text{days}} \times \text{chamber fraction}
\]  

(1)

Where \(Cell\ flux\) is in valves m\(^{-2}\) d\(^{-1}\), \(N_{\text{diat}}\) is the number of cells enumerated for each diatom classification, \(d\) is the dilution factor from the original wet aliquot, 8 is the total number of wet aliquots comprising one sample cup, \(V_{\text{cup}}\) is the volume of each wet aliquot, 0.125 is the Technicap PPS/3 sediment trap collecting area (m\(^2\)), \(\text{days}\) is the collecting period, \(\text{chamber fraction}\) is the surface fraction of the counting chamber that was observed (one quarter or one half). The annually integrated full and empty diatom flux for each species was calculated assuming as follows:

\[
Annual\ flux(x) = \sum_{i=1}^{12} (Flux(x)_i \times days_i)
\]  

(2)

Where \(Annual\ flux(x)\) is the annually integrated flux of a full or empty diatom species \(x\) (cell m\(^{-2}\) y\(^{-1}\)), \(Flux(x)_i\) is the full or empty flux of this species in the cup number \(i\) (cell m\(^{-2}\) d\(^{-1}\)) and \(days_i\) is the collecting time for the cup number \(i\) (d). The calculations assume negligible export occurred during the month of September which was not sampled by the sediment trap. We consider this assumption reasonable based on the preceding flux profile and low concentration of satellite-derived chlorophyll \(a\) (Rembauville et al. 2014).

We directly compared the micropaleontological (as used in Rigual-Hernández et al. (2015)) and biological counting techniques in our sediment trap samples and noted the loss of several species (\(Chaetoceros decipiens, Chaetoceros dichaeta, Corethron pennatum\) \(Corethron inerme, Guinardia cylindrus\) and \(Rhizosolenia chunii\)) under the
micropaleontological technique. We attribute this to the aggressive chemical oxidation

techniques used to “clean” the samples as well as the centrifugation steps which may also
selectively destroy or dissolve certain frustules. For the species that were commonly observed
by both techniques, total valve flux was in good agreement (Spearman rank correlation, $n =
12$, $\rho = 0.91$, $p < 0.001$, data not shown) although consistently lower with the
micropaleontological technique, probably due to the loss of certain frustules described above.

Full details of this method comparison are in preparation for a separate submission.

Diatoms species that contributed to more than 1 % of total full cell flux were
converted to carbon flux. For *E. antarctica* var. *antarctica*, *Fragilariopsis kerguelensis*,
*Fragilariopsis separanda/rhombica*, *Pseudo-nitzschia* spp. and *Thalassionema nitzschioides*
spp., we used published cell-specific carbon content (Cell$_C$, pgC cell$^{-1}$) for diatoms
communities of the Kerguelen Plateau from Cornet-Barthaux et al. (2007). As *Chaetoceros*
*Hyalochaete* resting spores (CRS) and *Thalassiosira antarctica* resting spores (TRS) largely
dominated the full diatom fluxes (>80%), an appropriate estimation of their carbon content
based on the specific sizes observed in our dataset was required for accurate quantification of
their contribution to carbon fluxes. Biomass calculations for both CRS and TRS were
determined from >50 randomly selected complete resting spores observed in splits from cups
#4 to #11 (December 2011 to May 2012). Morphometric measurements (pervalvar and apical
axis) were made using the Fiji image processing package (available at [http://fiji.sc/Fiji](http://fiji.sc/Fiji)) on
images taken with an Olympus DP71 camera. Cell volumes followed appropriate shape
designated calculations from Hillebrand et al. (1999) (Table 2). The cell volume coefficient of
variation was 46 % and 54 % for CRS and TRS, respectively. CRS carbon content was
estimated from the derived cell volume using the volume to carbon relationship of 0.039
pmolC µm$^{-3}$ established from the resting spore of *Chaetoceros pseudocurvisetus* (Kuwata et
al., 1993), leading to a mean Cell$_C$ value of 227 pgC cell$^{-1}$ (Table 2). There is currently no
volume to carbon relationship for *Thalassiosira antarctica* resting spores described in the literature, therefore, the allometric relationship for vegetative diatoms (Menden-Deuer and Lessard, 2000) was used to calculate our TRS carbon content, giving a mean $Cell_C$ value of 1428 pgC cell$^{-1}$ (Table 2). Full diatom fluxes were converted to carbon fluxes as follows:

$$ C_flux(x) = \frac{Flux(x) \times Cell_C(x)}{M_{12C} \times 10^9} \quad (3) $$

where $C_flux(x)$ is the carbon flux carried by each diatom species $x$ (mmol C m$^{-2}$ d$^{-1}$), $Flux(x)$ is the full cell numerical flux of species $x$ (cell m$^{-2}$ d$^{-1}$), $Cell_C(x)$ is the carbon content of species $x$ (pgC cell$^{-1}$) and $M_{12C}$ is the molecular weight of $^{12}$C (12 g mol$^{-1}$) and $10^9$ is a conversion factor from pmol to mmol.

### 2.3 Faecal pellet composition and fluxes

To enumerate faecal pellets an entire 1/8 aliquot of each sample cup was placed in a gridded petri dish and observed under a stereomicroscope (Zeiss Discovery V20) coupled to a camera (Zeiss Axiocam ERc5s) at 10x magnification. Photographic images (2560 x 1920 pixels, 3.49 µm pixel$^{-1}$) covering the entire surface of the petri dish were acquired. Following Wilson et al. (2013), faecal pellets were classified into five types according to their shape: spherical, ovoid, cylindrical, ellipsoid and tabular. The flux of each faecal pellet class (nb m$^{-2}$ d$^{-1}$) was calculated as follows:

$$ Faecal\ \text{pellet}\ \text{flux} = N_{FP} \times 8 \times \frac{1}{0.125} \times \frac{1}{\text{days}} \quad (4) $$

where $N_{FP}$ is the number of pellets within each class observed in the 1/8th aliquot. The other constants are as described in Eq. (1). Individual measurements of the major and minor axis for each faecal pellet were performed with the Fiji software. The total number of spherical, ovoid, cylindrical, ellipsoid and tabular faecal pellets measured was 4041, 2047, 1338, 54 and 29,
respectively. Using these dimensions, faecal pellet volume was determined using the appropriate shape equation (e.g. sphere, ellipse, cylinder, ovoid/ellipse) and converted to carbon using a factor of 0.036 mgC mm\(^{-3}\) (Gonzalez and Smetacek, 1994). Due to the irregularity of the tabular shapes preventing the use of single equation to calculate their volume, a constant value of 119 µgC pellet\(^{-1}\) representing a midrange value for tabular shapes (Madin, 1982), was applied to tabular faecal pellets (Wilson et al., 2013). This value was appropriate because the observed tabular faecal pellets were within the size range reported in Madin (1982). Ranges and mean values of faecal pellet volumes and carbon content are reported in Table 3. Faecal fluff and disaggregated faecal pellets were not considered in these calculations because quantitative determination of their volume is difficult. We acknowledge that fragmentation of larger pellets may represent an artifact of the sample splitting procedure. Alternatively, their presence may also result from natural processes within the water column, although dedicated sampling techniques (e.g. polyacrylamide gel traps) are required to make this distinction (Ebersbach et al., 2014, 2011; Ebersbach and Trull, 2008; Laurenceau et al., 2014). Consequently our present quantification of faecal pellet carbon flux should be considered as lower-end estimates.

The precision of our calculations depends on the reliability of carbon-volume conversion factors of fecal pellets, which vary widely in the literature, as well as variability in diatom resting spore volumes (Table 2). To constrain the importance of this variability on our quantitative estimation of C flux, we calculated upper and lower error bounds by a constant scaling of the conversion factors (± 50 %).

### 2.4 Statistical analyses

Correspondence analysis was performed to summarize the seasonality of diatom export assemblages. This approach projects the original variables (here full and empty cells) onto a
few principal axes that concentrate the information of the Chi-squared (Chi\(^2\)) distance between both observations and variables (Legendre and Legendre, 1998). Chi\(^2\) distance is very sensitive to rare events. Consequently, only species with an annual mean flux higher than 10% of the mean annually integrated flux of all the species were retained in the correspondence analysis. This selection was performed separately on full and empty cell fluxes.

Partial least square regression (PLSR) analysis was used to examine the relationships between ecological flux vectors (full and empty diatom cells and faecal pellet fluxes as columns of the X matrix, cups being the rows) and bulk geochemical properties (POC flux, PON flux, BSi flux, POC:PON and BSi:POC molar ratio and columns in the Y matrix) of the exported material. The principle of PLSR is to decompose both the X and Y matrix into their principal components using principal component analysis and then use these principal components to regress Y in X (Abdi, 2010). PLSR is capable of modeling response variables from a large set of predictors. The same filter as for the correspondence analysis (full- and empty-cell fluxes >10 % of the total mean flux) was applied.

3 Results

3.1 Chemical composition of the settling material

Time series of the chemical signature of the settling material are presented in Fig. 1 and export fluxes are reported in Table 1. POC and PON fluxes are already reported and discussed in the companion paper (Rembauville et al., 2014). BSi fluxes exhibited the same seasonal pattern as POC fluxes (Fig. 1c) with low fluxes (< 1 mmol m\(^{-2}\) d\(^{-1}\)) except during the two intense events (2.60 ± 0.03 and 2.19 ± 0.10 mmol m\(^{-2}\) d\(^{-1}\), mean ± standard deviation). LSi fluxes were highest in spring (>10 µmol m\(^{-2}\) d\(^{-1}\) in cups #1 to #4, October to December 2011, Table 1). The contribution of LSi to total particulate Si was 5 % and 10 % respectively.
in cups #1 (October/November 2011) and #12 (May to September 2012) and lower than 3 % the remainder of the year. The BSi:POC molar ratio was highest at the beginning of the season (between 2.18 ± 0.19 and 3.46 ± 0.16 in the first three cups from October to December 2011, blue line in Fig. 1c) and dropped to 0.64 ± 0.06 in cup #5 (end December 2011), following the first export event. BSi:POC ratios were close in the two export events (1.62 ± 0.05 and 1.49 ± 0.08). The lowest BSi:POC ratio was observed in autumn in cup #11 (0.29 ± 0.01, February to May 2012). Similarly, the opal contribution to total mass flux was highest in spring (70.8 % in cup #2, November 2011) and lowest in autumn (21.5 % in cup #11, February to May 2012).

3.2 Diatom fluxes

Diatoms from 33 taxa were identified and their fluxes determined across the 11-months time series. Fluxes are reported in Table 4 and Table 5 for full and empty cells, respectively. Full and empty cell fluxes for the total community and for the taxa that are the major contributors to total diatom flux (eight taxa that account for >1 % of total cells annual export) are presented in Fig. 2. The full and empty cell fluxes for each diatom species or taxa are reported in Table 4 and 5, respectively.

During spring (cups #1 to #3, October to December 2011) and autumn/winter (cups #11 and #12, February to September 2012) the total flux of full cells was < 5 × 10^6 cells m^-2 d^-1 (Fig. 2a). The total flux of full cells increased to 5.5 and 9.5 × 10^7 cells m^-2 d^-1 (cups #4 and #9, December and end January respectively) during two episodic (<14 days) sedimentation events. The two largest flux events (cups #4 and #9) were also associated with significant export of empty cells with respectively 6.1 × 10^7 and 2.9 × 10^7 cells m^-2 d^-1 (Fig. 2a). For Chaetoceros Hyalochaete spp. resting spores (CRS), full cells fluxes of 4 × 10^7 cells m^-2 d^-1 and 7.8 × 10^7 cells m^-2 d^-1 accounted for 76 % and 83 % of the total full cell flux during these
two events, respectively (Fig. 2b), whereas a smaller contribution of *Thalassiosira antarctica* resting spores (TRS) \((2.7 \times 10^6 \text{ cells m}^{-2} \text{ d}^{-1}, 5 \% \text{ of total full cells})\) was observed during the first event (Fig. 2h). CRS also dominated (79-94 \% \text{ of the composition of full cells in the intervening period (cups #5-#8, December 2011 to January 2012)}, although the magnitude of cell flux was moderate \((9 \times 10^6 - 2.5 \times 10^7 \text{ cells m}^{-2} \text{ d}^{-1})\) by comparison (Fig. 2b). In cup #4 (December 2011), the empty cell flux contained 61 \% \text{ of *C. Hyalochaete* spp. vegetative empty cells and 27 \% of unidentified Small centrics (<20 \mu m) empty cells}. In cup #9 (end January 2012), the total empty cells flux contained 60 \% \text{ of *C. Hyalochaete* spp. vegetative stage and only 2 \% of Small centrics (<20 \mu m) empty cells}.

*Fragilariopsis kerguelensis*, and *Fragilariopsis separanda/rhombica* (Fig. 2d and 2e) were mostly exported from spring through the end of summer (cups #1 to #10, October 2011 to February 2012) with total (full + empty) fluxes < 3 \times 10^6 \text{ cells m}^{-2} \text{ d}^{-1}, a value ~20 times lower than the highest CRS fluxes recorded. During this time, these species were represented by >50 \% of empty cells. In autumn and winter, (cups #10 and #11, February to May 2012), these species were only represented by low fluxes (< 0.5 \times 10^6 \text{ cells m}^{-2} \text{ d}^{-1}) \text{ of empty cells}. *Thalassionema nitzschioides* spp. fluxes were highest in spring and early summer (cups #1 to #4, October to December 2011) with total fluxes comprised between 3.5 \times 10^6 \text{ and } 6.7 \times 10^6 \text{ cells m}^{-2} \text{ d}^{-1} \text{ (Fig. 2g)}. The remainder of the year, total flux was < 2 \times 10^6 \text{ cells m}^{-2} \text{ d}^{-1} \text{ and was essentially represented by full cells}. *Pseudo-nitzschia* spp. were mostly represented by full cells (Fig. 2f) with the highest flux of 1.2 \times 10^7 \text{ cells m}^{-2} \text{ d}^{-1} \text{ observed in the second intense export event (cup #9, end January 2012)}. *Eucampia antarctica* var. *antarctica* total fluxes were always represented by >50 \% of full cells (Fig. 2c). Total cell fluxes of *Eucampia antarctica* var. *antarctica* gradually increased from <1 \times 10^5 \text{ to } 1.3 \times 10^6 \text{ cells m}^{-2} \text{ d}^{-1} \text{ from spring to summer (cups #1 to #9, October 2011 to January 2012)} \text{ and then decreased to a negligible flux in winter (cup #12, May to September 2012)}. This species was observed as
both the lightly silicified, chain-forming, vegetative form and the highly silicified winter
growth stage form. Both forms were observed throughout the year without specific seasonal
pattern. Small centric species (<20 µm) were essentially represented by empty cells (Fig. 2i).
Their total fluxes were $<4 \times 10^6$ cells m$^{-2}$ d$^{-1}$, except in the first export event (cup #4,
December 2011) where their flux represented a considerable export of $1.7 \times 10^7$ cells m$^{-2}$ d$^{-1}$.

Diatoms and sampling cup projection on the first two axes from the correspondence
analysis is presented in Fig. 3. Chi$^2$ distance in the correspondence analysis is based on
frequency distribution, therefore the results of the analysis must be considered as
representative of the community composition as opposed to cell flux. The first two factors
accounted for the majority (75.6 %) of total explained variance. Early in the season (cups #1-
#3, October to mid-December 2011), during the period of biomass accumulation in the
surface (Fig 1a), diatom fluxes were characterized by empty cells of *T. nitzschioides* spp. and
*F. kerguelensis*. Full TRS cells were observed in cup #3 (end November 2011) following the
initial bloom decline. The first major flux event (cup #4, December 2011) contained mostly
TRS, empty Small centrics (< 20 µm) cells and empty *C. Hyalochaete* spp. cells. The summer
flux period (cups #5 to #8, December 2011 to January 2012) primarily consisted of CRS,
although *E. antarctica* var. *antarctica*, *Pseudo-nitzschia* spp. and *Thalassiotrix antarctica*
were present as full cells and *Plagiotropis* spp., *Membraneis* spp., *Pseudo-nitzschia* spp. as
empty cells. The second major flux event (cup #9, end January 2012) was tightly associated
with CRS and full *Pseudo-nitzschia* spp. cells. Subsequent cups (#10 and #11, February to
May 2012) were characterized by full cells of *E. antarctica* var. *antarctica* and *Thalassiotrix
antarctica* and empty cells of *Corethron inerme, P. alata, F. separanda/rhombica* and *F.
kerguelensis*. Winter fluxes (cup #12, May to September 2012) were similar to the initial three
cups characterized primarily by empty cells of small diatom taxa. The centralized projection
in Fig. 3 of full *F. kerguelensis* and *T. nitzschioide*s spp. highlights their constant presence throughout the annual record.

The total empty:full cell ratio is presented in Fig. 2a (blue line). This ratio was highest in spring and early summer (cups #1 to #4, October to December 2011), ranging between 1.1 and 2.4, suggesting more empty cells to full cells. The ratio was lowest, representing considerably more full cells to empty cells in cups #5 to #10 (December 2011 to February 2012) with values between 0.1 and 0.4. In autumn (cup #11, February to May 2012), the empty:full ratio increased to 0.7. In the winter cup #12 (May to September 2012), the total amount of full diatom cells was very low and therefore we could not calculate a robust empty:full ratio. Across the time-series certain diatom taxa were observed exclusively as empty cells, notably *Chaetoceros atlanticus* f. *bulbosum*, and *Corethron pennatum*. For diatom taxa present as full and empty cells we calculated an annually integrated empty:full ratio (Fig. 4) and arbitrarily defined threshold values of 2 (representing species mainly observed as empty cells) and 0.5 (representing species mainly observed as full cells), respectively. In decreasing order, the diatom taxa exhibiting empty:full ratios >2 were *Thalassiosira lentiginosa*, Small centrics (<20 µm), *Proboscia alata*, *Rhizosolenia antennata/styiformis*, *Chaetoceros decipiens*, *Corethon inerme*, *Dactyliosolen antarcticus*, Large centrics (>20 µm), and *Asteromphalus* spp. The diatom taxa displaying an empty:full ratio <0.5 were *Thalassiothrix antarctica*, *Rhizosolenia simplex*, *CRS*, *Eucampia antarctica* var. *antarctica*, *Thalassiosira* spp. and *Navicula* spp. Species or grouped taxa with ratio values falling between the thresholds <2 and >0.5 (*R. chunii*, through to *C. dichae*ta in Fig. 4) were perceived as being almost equally represented by full and empty cells when integrated annually across the time series.

### 3.3 Faecal pellet fluxes
The seasonal flux of faecal pellet type, volume and their estimated carbon flux are summarized in Fig. 5 and Table 6. Total faecal pellet flux was \(<2 \times 10^3\) pellets m\(^{-2}\) d\(^{-1}\) in spring (cups #1 to #3, October to December 2011). Cups #4 and #5 (December 2011) were characterized by the highest fluxes of $21.8 \times 10^3$ and $5.1 \times 10^3$ pellets m\(^{-2}\) d\(^{-1}\) (Fig. 5a, Table 6). Faecal pellet numerical flux decreased gradually from mid-summer (cup #5, December 2011) to reach a minimal value in winter (140 pellets m\(^{-2}\) d\(^{-1}\) in cup #12, May to September 2012). In spring (cups #1 to #3, October to December 2011), spherical and cylindrical shapes dominated the numerical faecal pellet fluxes. Ellipsoid and tabular shapes were absent from these spring cups. The first export event (cup #4, December 2011), was numerically dominated by the spherical shaped pellets, however the remainder of the summer (cups #5 to #10, December 2011 to February 2012) contained spherical, ovoid and cylindrical shapes in comparable proportions. Ellipsoid shapes were observed from mid-summer to autumn (cups #7 to #11, January to May 2012) but their overall contribution to pellet flux was low (<6 %, Table 6). Rare tabular shapes were observed in summer (cups #6 and #8, December and January 2012) and their contribution to numerical fluxes was highest in autumn and winter (cups #11 and #12, February to September 2012).

The median faecal pellet volume showed a seasonal signal with a maximum peak $>5.5 \times 10^6$ \(\mu\)m\(^3\) in mid-summer (cups #6 to #8, mid-December to January 2012) and values $<4 \times 10^6$ \(\mu\)m\(^3\) the remainder of the year (Fig. 5b). Concomitantly with the highest median volume, the largest variance in faecal pellet size was also observed in the summer (highest interquartile values in Fig. 5b).

Total faecal pellet carbon flux was lowest in spring ($<0.05$ mmolC m\(^{-2}\) d\(^{-1}\) in cups #1 to #3, October to December 2011, Fig. 5c, Table 6). The highest total faecal pellet carbon flux of nearly 0.5 mmolC m\(^{-2}\) d\(^{-1}\) was observed during the first export event in cup #4 (December 2011) and was essentially composed of spherical shapes (83 %, Table 6). For the remainder of
the summer (cups #5 to #10, December 2011 to February 2012), total faecal pellet carbon flux was between 0.03 and 0.15 mmolC m$^{-2}$ d$^{-1}$ with a dominant contribution of cylindrical, ellipsoid and tabular shapes. In autumn and winter (cups #11 and #12, February to September 2012), faecal pellet carbon fluxes of 0.13 and 0.06 mmolC m$^{-2}$ d$^{-1}$ were strictly dominated by tabular shapes (>90% to total faecal pellet carbon fluxes, Table 6).

3.4 Statistical analysis of biological and biogeochemical signatures

The β correlation coefficients of standardized variables obtained from the PLSR analysis are presented as a heatmap in Fig. 6. The full cell fluxes of all diatom taxa, in addition to spherical and ovoid and ellipsoid faecal pellet fluxes were positively correlated to POC and PON fluxes. By contrast, empty cell fluxes of *F. kerguelensis*, *P. alata*, *T. nitzschioïdes* spp., *T. lentiginosa* and cylindrical, ellipsoid and tabular pellet fluxes were either uncorrelated or negatively correlated with POC and PON fluxes. Full- and empty-cell fluxes of all diatom taxa were positively correlated with BSi fluxes, although this correlation was notably weak for empty cells of *C. inerme*, *P. alata* and *T. lentiginosa*. Only spherical and ovoid faecal pellets were positively correlated with BSi fluxes. Full cells fluxes of CRS and *E. antarctica* var. *antarctica* were the most negatively correlated with BSi:POC molar ratio, whereas TRS, *F. kerguelensis*, *T. nitzschioïdes* spp. and *T. lentiginosa* full cells fluxes were positively correlated. Spherical and ovoid faecal pellets were weakly and negatively correlated with the BSi:POC molar ratio whereas the cylindrical, ellipsoid and tabular shapes were more strongly negatively correlated to the BSi:POC molar ratio. All the biological components exhibited weak or no correlations to the POC:PON molar ratio.

The first two latent vectors of the PLSR accounted for 61.3 % and 74.1 % of cumulative variance in X (full and empty diatom and pellet fluxes) and Y (biogeochemical properties). In order to visualize how the seasonal succession of flux vectors was related to
the bulk geochemical properties of particles, the sampling cups, biological and chemical factors were projected on the first two latent factors of the PLSR analysis (Fig. 7). Positively projected on the first axis are the POC, PON and BSi fluxes, close to the export events sampled in cups #4 (December 2011) and #9 (end January 2012). The closest biological components comprise a complex assemblage of full and empty cells and spherical and ovoid faecal pellet shapes. All the other cups are projected far from these two export events. The second axis opposes the spring cups (#1 to #3, October to mid-December 2011) to the autumn (#11, February to May 2012) and winter (#12, May to September 2012) cups. Empty frustules of *F. kerguelensis*, *T. lentiginosa* and *T. nitzschioides* spp. are projected close to the spring cups (#1 to #3, October to mid-December 2011) together with the BSi:POC molar ratio whereas autumn (#11, February to May 2012) and winter cups (#12, May to September 2012) are projected far from the BSi:POC molar ratio and close to the tabular and cylindrical faecal pellet shapes.

### 3.5 Partitioning carbon fluxes among ecological vectors

We estimated the contribution of resting spores and faecal pellets to carbon flux, calculated their cumulative values and compared them to measured values (Fig. 8a and 8b). A highly significant correlation (Spearman rank correlation, n= 36, ρ = 0.84, p < 0.001) was evident between calculated and measured carbon flux suggesting that the main ecological flux vectors observed in the sample were capable of explaining the seasonal variation in total POC flux. Table 7 lists the contribution of each vector to the calculated flux. In cup #1 (October to mid-November 2011), CRS and other diatoms dominated the calculated POC fluxes, with respectively 25.3 % and 38.6 %. Diatoms other than spores dominated the calculated carbon flux (35.4 %) together with cylindrical faecal pellets (36.4 %) in cup #2 (November 2011). TRS dominated the POC fluxes (85.1 %) in cup #3 (November/December 2011). CRS strictly dominated the calculated POC fluxes in summer (cups #4 to #10, December 2011 to February
2012) with a contribution ranging from 46.8 % to 88.1 %. During the autumn and winter (cups #11 and #12, February to September 2012), POC fluxes were almost exclusively associated to tabular faecal pellets, 81 % and 93.3 %, respectively. At annual scale diatoms resting spores (CRS and TRS), other diatoms and faecal pellets respectively accounted for 60.7 %, 5 % and 34.3 % of the calculated POC fluxes. Annual POC fluxes estimated from ecological vectors considered here were slightly less than measured values (93.1 versus 98.2 mmol m$^{-2}$).

4 Discussion

4.1 The significance of resting spores for POC flux

In a companion paper we present multiple lines of evidence that converge on a scenario of strong flux attenuation between the base of the winter mixed layer (WML at ~220 m) and 300 m on the Kerguelen Plateau (Rembauville et al., 2014). Most notably large attenuation coefficients (3.3 – 4) were calculated from independent measurements in spring and summer (Ebersbach and Trull, 2008; Jouandet et al., 2014). Strong flux attenuation and under trapping due to hydrodynamics and swimmers combine to explain the low annually-integrated POC fluxes. Generally POC fluxes were <0.5 mmol m$^{-2}$ d$^{-1}$ with the notable exception of two pulsed (<14 days) export events of ~1.5 mmol m$^{-2}$ d$^{-1}$ that accounted for ~40 % of annual POC export. These two flux events were characterized by a noticeable increase and general dominance of diatom resting spores. During both of these pulsed export events, cumulative Chaetoceros Hyalochaete spp. resting spores (CRS) and Thalassiosira antarctica resting spores (TRS) fluxes accounted for 66 % and 88 % of the measured POC flux, whereas total faecal pellet flux accounted for 29 % and 5.2 %, respectively (Table 7). The combination of CRS and TRS were responsible for 60.7 % of the annual calculated POC flux, a value ten times higher than the contribution of other diatoms (5 %). We did not observe any full cells of
the vegetative stage of *Chaetoceros Hyalochaete*, a feature possibly related to its high susceptibility to grazing pressure in the mixed layer (Smetacek et al., 2004; Quéguiner, 2013; Assmy et al., 2013). Empty *Chaetoceros Hyalochaete* spp. cells were vegetative stages different in shape from the resting spores. These empty frustules may be the remnants of vegetative stages following spore formation. Alternatively, dissolution of the lightly silicified valves or girdle bands of the vegetative cell could result in the rapid consumption of the cellular organic material in the upper water column and this may also explain the absence of full vegetative cells in the sediment trap record. Our flux data reveal that small (10 to 30 µm) and highly silicified resting spores bypass the intense grazing pressure characterizing the base of the mixed layer, and are the primary mechanism through which carbon and, to a lesser extent silicon, is exported from the surface.

Numerous sediment trap studies have reported a strong contribution, if not dominance, of CRS to diatom fluxes at depth in various oceanographic regions: firstly, in coastal influenced regions (e.g. Antarctic Peninsula (Leventer, 1991), Bransfield Strait (Abelmann and Gersonde, 1991), Gulf of California (Sancetta, 1995), the Omura Bay (Kato et al., 2003), Santa Barbara basin (Lange, 1997), North Pacific Ocean (Chang et al., 2013) and the Artic (Onodera et al., 2014)), secondly in upwelling-influenced regions (e.g. Santa Barbara basin (Lange, 1997), Eastern Equatorial Atlantic (Treppke et al., 1996)) and finally in the open ocean in the subarctic Atlantic (Rynearson et al., 2013). Similar to sediment trap observations, CRS are reported as dominant in surface sediments of coastal regions (peri-Antarctic shelf and Antarctic sea ice (Crosta et al., 1997; Zielinski and Gersonde, 1997; Armand et al., 2005), the North Scotia Sea (Allen et al., 2005) and east of Kerguelen Island (Armand et al., 2008b)), but also in upwelling-influenced regions (the northeastern Pacific (Grimm et al., 1996), the northeast Pacific (Lopes et al., 2006)) and finally in the open ocean (the North Atlantic, Bao et al., 2000). Moreover, the annual POC export from the A3 station sediment trap at 289 m
(98.2±4.4 mmol m$^{-2}$ y$^{-1}$) falls near annual estimates from deep sediment traps (>2000 m) located in the naturally fertilized area downstream of the Crozet Islands (37-60 and 40-42 mmol m$^{-2}$ y$^{-1}$, Salter et al., 2012) where fluxes were considered as mainly driven by resting spores of *Eucampia antarctica* var. *antarctica*. Diatom resting spores are frequently observed in blooms heavily influenced by the proximity of the coast. Major resting spores contribution to carbon fluxes was observed in only one study in the open North Atlantic Ocean (Rynearson et al., 2013), but they are generally absent or very rare in open ocean sediment trap studies (Fischer et al., 2002; Grigorov et al., 2014; Rigual-Hernández et al., 2015). The frequent occurrence and widespread distribution of diatoms resting spores in the neritic or coastal-influenced ocean suggest their pivotal role in the efficient transfer of carbon to depth in these areas.

*Chaetoceros* resting spores have been reported to contain up to 10 times more carbon than the vegetative forms (Kuwata et al., 1993) with no vacuole and high contents of lipids and carbohydrates (Doucette and Fryxell, 1983; Kuwata et al., 1993). Moreover, CRS resist grazing and have been found to lower copepods grazing pressure (Kuwata and Tsuda, 2005). We suggest that diatom resting spores gather three essential characteristics for effective POC export to the deep ocean: (1) they efficiently bypass the grazing pressure near the mixed layer due to their morphological characteristics such as very robust frustules (CRS) or numerous spines (TRS) (high export efficiency), (2) they are efficiently transferred to depth due to the thick and dense frustule increasing sinking velocity and (3) their high carbon content is protected from microbial degradation by the thick frustules (these last two points result in a high transfer efficiency). The spatial distribution and formation of resting spores may therefore be an integral ecological component defining the strength and efficiency of the biological pump in specific regions. Nutrient depletion has been shown to trigger resting spore formation in *Chaetoceros Hyalochaete* laboratory cultures (Garrison, 1981; Sanders and
over relatively rapid timescales (6 to 48 h, McQuoid and Hobson, 1996). Although Si(OH)\(_4\) depletion appears to be the most likely biogeochemical trigger at the Kerguelen Plateau (from 24 \(\mu\)mol L\(^{-1}\) in early spring to 2 \(\mu\)mol L\(^{-1}\) in summer, (Mosseri et al., 2008; Closset et al., 2014)), other environmental factors (iron or light availability) could influence the resting spore formation. Notably, dissolved iron concentration in the mixed layer rapidly decreases to 0.1~0.2 nmol L\(^{-1}\) after the beginning of the spring bloom at A3, however the vertical entrainment is much weaker in summer compared to spring (Bowie et al., 2014). Rynearson et al. (2013) reported the absence of spores in the mixed layer despite a strict dominance into the trap samples. A resting spore formation at some depth (possibly implying a light control) would explain the temporal decoupling between the surface production tracked by the satellite in the surface layer (first ~20 meters) and the export events. Further work to establish seasonal dynamics of these factors linked to diatom life cycles and specifically the formation of resting spore is necessary.

### 4.2 Contribution of faecal pellets to POC flux

Although diatom resting spores are the primary vector for POC flux below the mixed layer, faecal pellets were also important and accounted for 34.3 % of annual export. It has been hypothesized that faecal pellets are the dominant flux component in High Biomass, Low Export (HBLE) environments, where biomass is routed to higher trophic levels (Lam and Bishop, 2007; Ebersbach et al., 2011). However, this hypothesis does not appear to be true for the bloom of the central Kerguelen Plateau suggesting that faecal material is efficiently reprocessed in the mixed layer, or that a significant part of the pellet flux is excreted below the trap depth by vertically migrating zooplankton. Small spherical faecal pellets dominated the annual numerical faecal pellet flux (53.8 %, Table 6). The short and intense export of small spherical faecal pellets was concomitant with the first strong POC export in cup #4
The significance of small spherical faecal pellets to POC flux is somewhat uncharacteristic in comparison to other sediment trap records in shallow areas of the Southern Ocean (Schnack-Schiel and Isla, 2005). They are possibly produced by small cyclopoid copepods, like *Oithona similis* that are abundant in the POOZ (Fransz and Gonzalez, 1995; Pinkerton et al., 2010). More specifically, *O. similis* represents >50% of mesozooplankton abundance at A3 in spring (Carlotti et al., 2015) has been observed at station A3 in summer (Carlotti et al., 2008). *Oithona* species are known to be coprophagous and play an important role in flux reprocessing (Gonzalez and Smetacek, 1994), which may partially contribute to the rapid flux attenuation observed by efficiently retaining carbon in the mixed layer. This reprocessing feeding strategy might also explain the low faecal pellet flux we observed (highest value of $21.8 \times 10^3$ pellet m$^{-2}$ d$^{-1}$), which was two orders of magnitude lower than the $>5 \times 10^5$ pellet m$^{-2}$ d$^{-1}$ observed in neritic areas where euphausiids dominate the mesozooplankton community (Bodungen, 1986; von Bodungen et al., 1987; Wefer et al., 1988).

There were notable differences in faecal pellet type over the course of the season. The transition from spherical and ovoid pellets in spring to larger cylindrical and tabular pellets in summer presumably reflects shifts in dominant zooplankton species from small cyclopoid copepods towards larger calanoid copepods, euphausiids and salps (e.g. Wilson et al., 2013). Carlotti et al. (2015) report that mesozooplankton biomass doubled between October and November 2011 and was three-fold higher in January 2005 (Carlotti et al., 2008). In spring, Carlotti et al. (2015) observed that the small size fraction (300 – 500 µm) was numerically dominated by *Oithona similis* (50% of the total mesozooplankton assemblage), although the larger size fractions dominated the mesozooplankton biomass (dominated by Clausocalanus citer, and *Rhicalanus gigas*). This is consistent with the dominance of small spherical faecal pellets and the lower contribution of cylindrical shapes we observed in spring and early
summer (cups #1 to #4, October to December 2011, Table 6). In summer (January 2005), the mesozooplankton community was more diversified and comprised 21% of small individuals (Oithona sp and Oncea sp.), 20% of medium-sized individuals (Clausocalanus sp and Microcalanus sp.) and 21% of large individuals (Calanus sp., Metrida sp., Paraeuchaeta sp., Pleuromama sp. and Rhincalanus sp.; Carlotti et al., 2008). As the median size of faecal pellets increases, so does their relative contribution to carbon flux (Fig. 5b and 5d, Table 6).

Our observation of an increasing contribution of cylindrical faecal pellet shapes in summer (cups #5 to #10, December 2011 to February 2012, Table 6) is consistent with the increasing contribution of large calanoid copepods to the mesozooplankton assemblages. We note that pteropods showed the highest contribution to mesozooplankton assemblages at station A3 in summer (16% of total abundance, Carlotti et al., 2008). We associate this observation with the large ellipsoid faecal pellet shape that was first observed in the sediment trap in cup #5 (end December 2011) and represented the highest contribution to faecal pellet carbon fluxes in cup #9 (January/February 2012, Table 7). Tabular faecal pellets dominated the low POC fluxes observed in the autumn and winter when chlorophyll a concentration was reduced to background levels, although this interpretation should be taken with caution since a constant and high carbon content was used for this shape. The increase in organic carbon content and negative correlation between the abundance of cylindrical, ellipsoid and tabular faecal pellets fluxes and the BSi:POC molar ratio suggests that large zooplankton producing these tabular pellets (large copepods, euphausiids and salps) were not feeding directly on diatoms. During the autumn and winter, microbial components other than diatoms must sustain the production of these large zooplankton. Direct observation of faecal pellet content is beyond the scope of the present study but would help to elucidate how seasonal trends of zooplankton feeding ecology influence carbon and biomineral export. Moreover, dedicated studies are still needed
to document the seasonal dynamic of euphausiid and salp abundances over the Kerguelen
Plateau to compare them with our reported faecal pellet fluxes.

4.3 Diatom fluxes

The diatom fluxes (sum of empty and full cells) observed at the central Kerguelen
Plateau reached their maximum value of $1.2 \times 10^8$ cells m$^{-2}$ d$^{-1}$ during the two short export
events, which is equivalent to $2.4 \times 10^8$ valves m$^{-2}$ d$^{-1}$. This latter value falls between the
highest values observed in POOZ ($\sim 10^7$ valves m$^{-2}$ d$^{-1}$, Abelmann and Gersonde, 1991; Salter
et al., 2012; Grigorov et al., 2014) and the SIZ ($>10^9$ valves m$^{-2}$ d$^{-1}$, Suzuki et al., 2001;
Pilskalin et al., 2004). The diatom fluxes over the Kerguelen plateau are similar to the 2.5 - 3.5
$\times 10^8$ valves m$^{-2}$ d$^{-1}$ measured at 200 m depth in a coastal station of the Antarctic Peninsula,
where CRS represented $\sim$80 % of the phytoplankton assemblage (Leventer, 1991). Previous
studies report the presence of a resting spore formation strategy in diatom species as typically
associated with neritic areas (Smetacek, 1985; Crosta et al., 1997; Salter et al., 2012). During
the summer KEOPS1 cruise, a shift in plankton community composition was observed at
station A3 between January and February. The surface community initially dominated by
*Chaetoceros Hyalochaete* vegetative chains gave way to one dominated by *Eucampia
antarctica* var. *antarctica*, concomitant with increasing CRS abundance in the mixed layer
(Armand et al., 2008a). The abundance of dead cells (within chains or as empty single cells
and half cells) in the surface water column also increased from January to February,
suggesting intense heterotrophic activity. Surface sediments at station A3 contain, in
decreasing abundance, *F. kerguelensis*, CRS and *T. nitzschioides* spp. cells (Armand et al.,
2008b). These sedimentary distributions are consistent with the dominant species observed in
the sediment trap, *F. kerguelensis* and *T. nitzschioides* spp. being present throughout the year
and mostly represented by empty cells whereas CRS are exported during short and intense
events.
Eucampia antarctica var. antarctica resting spores dominated the deep (2000 m) sediment trap diatom assemblages in the naturally fertilized area close to the Crozet Islands with fluxes > $10^7$ cells m$^{-2}$ d$^{-1}$ (Salter et al., 2012). We observed highest Eucampia antarctica var. antarctica full cells fluxes of $\sim 10^6$ cells m$^{-2}$ d$^{-1}$ in summer, which represents <10 % of the total cell flux. Both vegetative and resting stages were observed. Our results suggest that Eucampia antarctica var. antarctica is unlikely to be a major driving vector for carbon fluxes to depth over the central Kerguelen Plateau, in part because the community was not forming massive highly-silicified, fast-sinking resting spores contrary to observations near the Crozet Islands. Moreover their biogeographic abundance distribution from sea floor observations suggests they are not dominant in this region of the plateau (Armand et al., 2008b). The iron-fertilized Crozet bloom is north of the Polar Front and dissolved Si(OH)$_4$ concentrations were depleted to 0.2 μmol L$^{-1}$ (Salter et al., 2007) compared to ~2 μmol L$^{-1}$ on the Kerguelen Plateau (Mosseri et al., 2008). It is possible, along with differences in iron dynamics between the two plateaus, that differences in nutrient stoichiometry favour bloom dynamics and resting spore formation of Chaetoceros Hyalochaete populations surrounding the Kerguelen Islands. Nevertheless, the increasing full cell flux of Eucampia antarctica var. antarctica from spring to summer in the sediment trap time series is consistent with the observations of an increasing abundance in the mixed layer at the station A3 in summer (Armand et al., 2008a).

Highest Pseudo-nitzschia spp. full cell fluxes were observed in summer, concomitantly with the second export peak (cup #9, end January 2012). Pseudo-nitzschia species are rarely found in deep sediment trap studies and are absent from sediment diatom assemblages, presumably due to their susceptibility to water column dissolution (Grigorov et al., 2014; Rigual-Hernández et al., 2015). The species Pseudo-nitzschia hemii has been reported to accumulate in summer in deep chlorophyll maximum in the Polar Frontal Zone (Kopczynska et al., 2001). Such deep biomass accumulation is hypothesized to benefit from
nutrient diffusion through the pycnocline (Parslow et al., 2001). These general observations are consistent with the peaks in *Pseudo-nitzschia* spp. fluxes we report in summer over the Kerguelen Plateau.

Although their fluxes were very low, species of the *Rhizosolenia* and *Proboscia* genera were mostly exported as empty cells at the end of summer and during autumn (cups #8 to #11, end January to May 2012), occurring in parallel with the full cell fluxes of the giant diatom *Thalassiothrix antarctica* (Table 4). It has been suggested that these species belong to a group of “deep shade flora” that accumulate at the subsurface chlorophyll maxima in summer with their large frustules protecting them from grazing pressure in stratified waters (Kemp and Villareal, 2013). Interestingly these species were also found in deep sediment traps located in a HNLC area south of the Crozet Plateau (Salter et al., 2012), as well as in subsurface chlorophyll maximum in HNLC waters of the Southern Ocean (Parslow et al., 2001; Holm-Hansen et al., 2004; Gomi et al., 2010). A subsurface chlorophyll maximum has previously been observed at 120 m on the Kerguelen Plateau (also station A3) during summer (Uitz et al., 2009) and appears to correspond to an accumulation of particles consisting of aggregates of large diatom species (Jouandet et al., 2011). The fact that *Rhizosolenia* spp. and *Proboscia* spp. were observed as empty cells whereas *Thalassiothrix antarctica* was mostly represented by full cells suggest species-specific grazing on these communities. There appears to be ecological differentiation within the “deep shade flora” that precludes describing a single effect on export stoichiometry. Moreover, on the Kerguelen Plateau, these species are not exported in “massive” proportions as the fall-dump hypothesis suggests (Kemp et al., 2000). The physical and biogeochemical factors responsible for their production and export are still to be determined, and should be investigated thoroughly given the potential importance that these species might have for export fluxes on a global scale (Kemp et al., 2000; Richardson et al., 2000; Kemp and Villareal, 2013).
4.4 Preferential carbon and silica sinkers

Unlike most previous sediment trap studies in the Southern Ocean, we used a counting technique that facilitated the identification of carbon and siliceous components of exported material. Although we lost a small degree of taxonomic resolution with this approach (see methods), it allowed us to avoid unnecessary assumptions concerning carbon content of exported diatoms and directly constrain the role of different species for carbon and silica export.

The annual BSi:POC ratio of the exported material (1.16) is much higher than the usual ratio proposed for marine diatoms of 0.13 (Brzezinski, 1985). Moreover, the BSi:POC ratio of the exported material in spring (2.1 to 3.4, cups #1 to #3, October to mid-December 2011) is significantly higher than the BSi:POC ratio of 0.32 ± 0.06 in the mixed layer of the same station during spring (Lasbleiz et al., 2014). Numerous chemical, physical, biological and ecological factors can impact BSi:POC ratios of marine diatoms (e.g. Ragueneau et al., 2006). However, the ten-fold differences in BSi:POC ratios of exported particles between spring and summer is unlikely to result only from physiological constraints set during diatoms growth (Hutchins and Bruland, 1998; Takeda, 1998). Previous comparisons in natural and artificially iron-fertilized settings have the highlighted importance of diatom community structure for carbon and silica export (Smetacek et al., 2004; Salter et al., 2012; Quéguiner, 2013; Assmy et al., 2013). The presence of different diatom species and their characteristic traits (e.g. susceptibility to grazing, apoptosis, viral lysis) are all likely to influence the flux of full and empty cells. Therefore, the net BSi:POC export ratio results from the net effect of species specific Si:C composition (Sackett et al., 2014) and the subsequent species-specific mortality pathway and dissolution. A significant correlation between BSi:POC and empty:full cells ratio (Spearman rank correlation, n = 12, ρ = 0.78, p < 0.05) suggests the latter acts as a first order control on the silicon and organic carbon export stoichiometry. Differences in
BSi:POC ratios between the mixed layer suspended particle stock and particles exported out of the mixed layer may be explained by the dominant sedimentation of empty diatom frustules that results from the grazing pressure by the zooplankton community and the intense carbon utilization by heterotrophic microbial communities (Christaki et al., 2014).

We classified species that were observed exclusively as empty cells, or sinking with an integrated empty:full ratio >2, as predominantly silica exporters and these included: *C. bulbosum, C. pennatum, P. truncata, R. antennata/stiliformis, A. hookeri, A. hyalinus, C. decipiens, C. inerme, D. antarcticus, P. alata, T. nitzschoides* spp., *T. lentiginosa*, and small centric species (< 20 µm). Although *F. kerguelensis, T. nitzschoides* spp. and *T. lentiginosa* were present through the entire season, their fluxes were highly correlated with BSi:POC ratios (Fig. 6) identifying these species as significant contributors to silica export. On the contrary resting spores and species that sink with a major contribution of full cells (integrated empty:full ratio <0.5) were identified as belonging to the preferential carbon sinkers: *C. Hyalochaete* spp., *E. antarctica* var. *antarctica, R. simplex* and *Thalassiothrix antarctica*. Among them, CRS and *E. antarctica* var. *antarctica* were the most negatively correlated to the BSi:POC ratio and were identified as key species for carbon export (Fig. 6). These observations are consistent with a previous study of natural iron fertilization that identified *C. pennatum, D. antarcticus* and *F. kerguelensis* as major silica sinkers and CRS and *E. antarctica* var. *antarctica* resting spores as major carbon sinkers downstream Crozet islands (Salter et al., 2012). During the EIFEX artificial fertilization experiment *C. Hyalochaete* vegetative stages were identified as major carbon sinker whereas *F. kerguelensis* was considered as strong silica sinker (Assmy et al., 2013). Notably, resting spore formation was not observed in the artificial experiment performed in the open ocean remote from coastal influence, and carbon export was attributed to mass mortality and aggregation of algal cells (Assmy et al., 2013). Nevertheless, a more detailed analysis of species-specific carbon and
silica content in the exported material is necessary to fully elucidate their respective roles on carbon and silica export.

4.5 Seasonal succession of ecological flux vectors over the Kerguelen Plateau

Although sediment trap records integrate cumulative processes of production in the mixed layer and selective losses during export, they provide a unique insight into the temporal succession of plankton functional types and resultant geochemical properties of exported particles characterizing the biological pump. The seasonal cycle of ecological vectors and associated export stoichiometry is summarized in Figure 7. The robustness of the relationship between measured and calculated POC fluxes (Fig. 8b) suggests that the main ecological flux vectors described from the samples are capable of predicting seasonal patterns of total POC fluxes. At an annual scale the calculated POC fluxes slightly underestimate the measured fluxes (93.1 versus 98.2 mmol m$^{-2}$). This might result from the minor contribution of full cells other than the diatoms species considered, aggregated material, organic matter sorbed to the exterior of empty cells and faecal fluff that was difficult to enumerate.

A scheme of phytoplankton and zooplankton communities succession in naturally-fertilized areas of the Southern Ocean was proposed by Quéguiner (2013). Spring phytoplankton communities are characterized by small, lightly silicified, fast growing diatoms associated with small microphageous copepods. In summer, the phytoplankton community progressively switches toward large, highly silicified, slow growing diatoms resistant to the grazing by large copepods. In this scheme carbon export occurs mostly in end summer through the fall dump. The species succession directly observed in our sediment trap samples differs somewhat to the conceptual model proposed by Quéguiner (2013), although the general patterns are similar. The diatom species exported in spring were F. kerguelensis, T. nitzschiodes spp., and small centric species (<20 µm), whilst in summer the comparatively very large (>200 µm) species of Proboscia sp., Rhizosolenia sp. and Thalassiothrix antarctica
were observed. However we observe that these species constituting the spring fluxes are exported almost exclusively as empty cells. The abundance of small spherical and ovoid faecal pellet suggests an important role of small copepods in the zooplankton (Yoon et al., 2001; Wilson et al., 2013), which was corroborated by the finding of dominant *Oithona similis* abundances in the spring mesozooplankton assemblages at station A3 (Carlotti et al., 2015). Therefore, our data suggests that spring export captured by the sediment trap was the remnants of a diatom community subject to efficient grazing and carbon utilization in, or at the basis of, the mixed layer, resulting in a BSi:POC export ratio > 2 (Table 1).

The main difference in our observations and the conceptual scheme of Quéguiner, (2013) is the dominance of *Chaetoceros Hyalochaete* resting spores to diatom export assemblages and their contribution to carbon fluxes out of the mixed layer in summer. Resting spores appear to efficiently bypass the “carbon trap” represented by grazers and might also physically entrain small faecal pellets in their downward flux. In mid-summer, faecal pellet carbon export is dominated by the contribution of cylindrical shapes. This appears to be consistent with an observed shift toward a higher contribution of large copepods and euphausiids to the mesozooplankton community in the mixed layer (Carlotti et al., 2008). However, CRS still dominate the diatom exported assemblage. The corresponding BSi:POC ratio decreases with values between 1 and 2 (Table 1). The fact that there are two discrete resting spore export events might be explained by a mixing event that injected Si(OH)$_4$ into the surface allowing the development of a secondary Si(OH)$_4$ limitation.

In the autumn and winter, diatom fluxes are very low and faecal pellet carbon export is dominated by cylindrical and tabular contributions consistent with a supposed shift to zooplankton communities dominated by large copepods, euphausiids, and salps (Wilson et al., 2013). The low BSi:POC ratios characterizing export at this time suggest that these communities feed primarily suspended particles (in the case of salps) and on micro- and
mesozooplankton or small diatoms, although direct measurements of faecal pellet content would be necessary to confirm this.

5 Conclusion

We report the chemical (particulate organic carbon and nitrogen, biogenic silica) and biological (diatom cells and faecal pellets) composition of material exported beneath the winter mixed layer (289 m) in a naturally iron-fertilized area of the Southern Ocean. Annually integrated organic carbon export from the iron-fertilized bloom was low (98 mmol m\(^{-2}\)) although biogenic silicon export was significant (114 mmol m\(^{-2}\)). Chaetoceros Hyalochaete and Thalassiosira antarctica resting spores accounted for more than 60% of the annual POC flux. The high abundance of empty cells and the low contribution of faecal pellets to POC flux (34%) suggest efficient carbon retention occurs in, or at the base of the mixed layer. We propose that in this HBLE environment, carbon-rich and fast-sinking resting spores bypass the intense grazing pressure otherwise responsible for the rapid attenuation of flux. The seasonal succession of diatom taxa groups was tightly linked to the stoichiometry of the exported material. Several species were identified as primarily “silica sinkers” e.g. Fragilariopsis kerguelensis and Thalassionema nitzschioides spp. and others as preferential “carbon sinkers” e.g. resting spores of Chaetoceros Hyalochaete and Thalassiosira antarctica, Eucampia antarctica var. antarctica and the giant diatom Thalassiothrix antarctica. Faecal pellet types described a clear transition from small spherical shapes (small copepods) in spring, larger cylindrical an ellipsoid shapes in summer (euphausiids and large copepods) and large tabular shape (salps) in fall. Their contribution to carbon fluxes increased with the presence of larger shapes.

The change in biological productivity and ocean circulation cannot explain the ~80 ppmv atmospheric pCO\(_2\) difference between the preindustrial era and the last glacial
maximum (Archer et al., 2000; Bopp et al., 2003; Kohfeld et al., 2005; Wolff et al., 2006).

Nevertheless, a simple switch in ‘silica sinker’ versus ‘carbon sinker’ relative abundance would have a drastic effect on carbon sequestration in the Southern Ocean and silicic acid availability at lower latitudes (Sarmiento et al., 2004; Boyd, 2013). The results presented here emphasize the compelling need for similar studies in other locations of the global Ocean that will allow identification of key ecological vectors that set the magnitude and the stoichiometry of the biological pump.

Figures captions.

Figure 1. a) Time series of the surface chlorophyll $a$ concentration averaged in a 100 km radius around the trap location. The black line represents the climatology calculated for the period 1997/2013, whilst the green line corresponds to the sediment trap deployment period (2011/2012). b) POC fluxes (grey bars) and C/N molar ratio (red line) of the exported material, c) BSi flux (light blue bars) and BSi:POC ratio (blue line). Errorbars are standard deviation on triplicates.

Figure 2. a) Total diatom cells fluxes (bars, left axis) and total empty:full cells ratio (blue line, right axis). b) to h) Fluxes of diatom cells from selected species identified as major contributors to diatom fluxes ( >1 % of total diatom fluxes). In b), full cells are Chaetoceros Hyalochaete resting spores and empty cells are the vegetative stage. Full cell fluxes are represented by grey bars whereas empty cell fluxes are represented by white bars.

Figure 3. Factorial map constituted by the first two axes of the correspondence analysis performed on the full and empty diatom cell fluxes. Red squares are cup projections with cup numbers specified, blue circles are full cell projections, white circles are empty cell projections. The size of the markers is proportional to their representation quality in this factorial map.

Figure 4. Annual ratio of empty to full cells for species observed as both forms. The dashed lines are the 0.5 and 2 ratio values. Chaetoceros Hyalochaete spp. full cells were only observed as resting spores.

Figure 5. a) Faecal pellet numerical fluxes partitioned among faecal pellet types, b) boxplot of faecal pellet volume. On each box, the central mark is the median, the edges of the box are the first and third quartiles, the whiskers extend to the most extreme data points comprised in 1.5 times the interquartile distance. c) faecal pellet carbon fluxes partitioned between the five
faecal pellet types. The two arrows represent the two strong POC export events (cup #4 and #9, December 2011 and end January 2012, respectively).

**Figure 6.** Heatmap representation of β correlation coefficients between the biological variables (empty and full-cell diatom and faecal pellet type fluxes) and the chemical variables (POC, PON, BSi, POC:PON and BSi:POC) resulting from the partial least square regression. Blue circles represent full diatom cells, white circles are empty diatom cells. Brown circles represent the faecal pellet type fluxes. The alphabetical labels within the symbols are used to identify the variable projections shown in Fig. 7. CRS: *Chaetoceros Hyalochaete* resting spores, TRS: *Thalassiosira antarctica* resting spores.

**Figure 7.** Projection of the cups (red squares) the biological factors (circles) and the chemical factors (green diamonds) in the first two latent vectors of the partial least square regression. Circled labels refer to the full and empty species listed in Fig. 6.

**Figure 8.** a) Grey bars in the background are measured POC fluxes, colored bars in the foreground are calculated POC fluxes partitioned among the main ecological vectors identified. b) Regression (r² = 0.72) between the measured and calculated POC fluxes. The correlation is highly significant (Spearman rank correlation, n = 36, ρ = 0.84, p < 0.001). Error bars were generated by increasing/decreasing the carbon/volume conversion factors by 50%. Black dashed line is the 1:1 relation, red line is the regression line, red dashed lines denotes the 99% confidence interval. CRS: *Chaetoceros Hyalochaete* resting spores, TRS: *Thalassiosira antarctica* resting spores.
