Abstract

Photosynthesis by marine diatoms contributes substantially to global biogeochemical cycling and ecosystem productivity. It is widely accepted that diatoms are extremely sensitive to changes in Fe availability, with numerous in situ experiments demonstrating rapid growth and increased export of elements (e.g. C, Si and Fe) from surface waters as a result of Fe addition. Less is known about the effects of Fe enrichment on the phenotypes of diatoms, such as associated changes in nutritional value, furthermore data on taxon-specific responses is almost non-existent. Enhanced supply of nutrient-rich waters along the coast of the subantarctic Kerguelen Island provide a valuable opportunity to examine the responses of phytoplankton to natural Fe enrichment. Here we demonstrate the use of synchrotron radiation Fourier Transform Infrared (SR-FTIR) microspectroscopy to analyse changes in the macromolecular composition of diatoms collected along the coast and plateau of Kerguelen Island, Southern Ocean. SR-FTIR microspectroscopy enabled the analysis of individual diatom cells from mixed communities of field-collected samples, thereby providing insight into in situ taxon-specific responses in relation to changes in Fe availability. Phenotypic responses were taxon-specific in terms of intraspecific variability and changes in proteins, amino acids, phosphorylated molecules, silicate and carbohydrates. In contrast to some previous studies, silicate levels increased under Fe enrichment, in conjunction with increases in carbohydrate stores. The highly abundant taxon *Fragilariopsis kerguelensis* displayed a higher level of phenotypic plasticity than *Pseudo-nitzschia* spp., while analysis of the data pooled across all measured taxa showed different patterns in macromolecular composition compared to those for individual taxon. This study demonstrates that taxon-specific responses to Fe enrichment may not always be accurately reflected by bulk community measurements, highlighting the need for further research into taxon-specific phenotypic responses of phytoplankton to environmental change.
1 Introduction

Growth of diatoms in the global ocean is estimated to contribute ~20% of the total primary productivity on Earth, thereby supporting substantial marine and terrestrial ecosystems, including fisheries which supply 15% of the world’s animal protein for human consumption (Armbrust, 2009; Mora et al., 2009; Nelson et al., 1995). As their frustules rain down to the deep ocean, diatoms export substantial quantities of C, Fe and Si from surface waters and determine the nutrient budget of the global ocean (Arrigo, 2005; Ingall et al., 2013; Le Quere et al., 2005). Diatoms are very sensitive to changes in Fe availability and rapidly form expansive blooms when the trace metal becomes available (Marchetti and Cassar, 2009). Fe limitation is known to cause changes in diatom morphology (such as reduced cell size), reduced photosynthetic efficiency, pigment levels and growth rates (Marchetti and Cassar, 2009). The critical role of diatoms in ocean biogeochemistry and ecosystem functioning merits further investigation of their phenotypic responses to environmental change.

Naturally Fe-enriched water near the Kerguelen Island supports the largest annual phytoplankton bloom (45,000 km²) in the high nutrient, low chlorophyll Southern Ocean (Quéguiner et al., 2007). The natural phenomenon of Fe enrichment in this region presents a valuable opportunity to study the effects of Fe perturbations on diatom growth, productivity, community composition, biogeochemistry and carbon export (Blain et al., 2007). Little is currently known about the effects of Fe on the macromolecular composition (i.e. carbohydrates, lipids, proteins and nucleic acids) of diatoms. The macromolecular composition is an important component of the phenotype, determining energy and nutrient fluxes available for higher trophic levels and influencing cellular carbon productivity (Andersen et al., 2004; Kroon and Thoms, 2006; Sackett et al., 2013).

Given the importance of diatoms to elemental cycling and marine ecosystem productivity, this study aimed to investigate the macromolecular responses of major groups of diatoms in waters near Kerguelen Island in relation to differences in Fe availability. Further, we demonstrate a novel, microspectroscopy-based approach to phenomics,
a discipline that has been flagged as critical to enhancing our ability to untangle the complex interaction of genotype and environment, and allow us to predict phenotypic traits such as species fitness (Houle et al., 2010).

Although it is generally accepted that the responses of phytoplankton communities to environmental factors vary between species, to date phenotypic (e.g. macromolecular, elemental and physiological) data from natural populations has been largely limited to bulk community or size fractionated measurements. The lack of taxon-specific macromolecular data relates to the large quantities of biomass generally required for biochemical analyses, difficulty sorting algal cells into taxonomic groupings, and to the time and financial costs associated with available measurement techniques. Recently however, elemental analysis of individual Southern Ocean phytoplankton cells using X-ray Fluorescence Microprobe Analysis has revealed species-specific changes in elemental composition with Fe availability (Twining et al., 2004a, b). Here we used synchrotron radiation Fourier Transform Infrared (SR-FTIR) microspectroscopy to analyse taxon-specific changes in macromolecular composition with Fe availability in individual diatom cells. SR-FTIR microspectroscopy is a powerful, non-invasive technique generating multivariate data on the total macromolecular composition of cells. The approach is growing in popularity among microbial ecologists and biomedical researchers (Murdock and Wetzel, 2009). The technique provides information on the macromolecular composition and physiological status of biological samples, without the need for lengthy extraction protocols because cells can be analysed non-invasively. The power of the technique relates not only to its high precision, but its ability to simultaneously provide information about the macromolecular composition and phenotypic parameters such as growth rate and phenotypic plasticity (Giordano et al., 2001; Heraud et al., 2007; Jebsen et al., 2012; Sackett et al., 2013). In addition, FTIR microspectroscopy has shown great promise as a tool for semi-automated taxonomic classification of microorganisms down to sub-species level (Naumann et al., 1991).

Here we present the first published macromolecular data collected from individual phytoplankton cells from the Southern Ocean using SR-FTIR spectroscopy. Cells were
analysed in hydrated form directly from sea water plankton haul samples, thereby minimizing artefacts related to sample preparation. The study aimed to measure phytoplankton macromolecular composition of cells of different taxa collected from stations with contrasting Fe levels. The macromolecular composition of individual cells from four dominant groups of phytoplankton (Fragilariopsis kerguelensis, Pseudo-nitzschia spp., Chaetoceros spp. and Eucampia antarctica v. antarctica) at four different sampling stations is compared (Table 1). The first two stations (E-1 and E-5) were sited within a complex recirculation system located in a stationary meander of the Polar Front, characterised by moderate phytoplankton biomass, moderate Fe levels and relatively low productivity and growth rates (Blain et al., 2014b). The second two stations (E4-W and TEW-8) received Fe-rich waters from the Kerguelen Island and Plateau, resulting in high phytoplankton biomass, high productivity and growth rates (Blain et al., 2014b). Additionally, the spectroscopic data was used to investigate the accuracy of the method for simultaneously classifying cells by taxa.

2 Materials and methods

2.1 Sampling

Twenty phytoplankton net stations (Phytonet stations 7 to 27, excluding station 23) were sampled for the purpose of SR-FTIR microspectroscopy analysis from October–December 2011 (Blain et al., 2014a). A 35 µm meshed phytoplankton net was deployed from the RV Marion Dufresne II to sample the top 100 m of the surface waters. Hauling speed was minimised to around 5 m min⁻¹. 100 mL samples were taken from each station immediately after the haul and fixed with formaldehyde (1–2 % final conc.). Fixed samples were kept at room temperature in the dark until analysis by SR-FTIR microspectroscopy. Additional 100 mL samples were preserved with Lugol’s iodine solution and analysed for diatom composition (Armand unpublished). Taxonomic iden-
Identification followed modern authority descriptions summarised in Hasle and Syvertsen (1997).

2.2 Microspectroscopy

Four taxa were selected for analysis based on their abundance within the samples at each site. These were *Fragilariopsis kerguelensis*, *Eucampia antarctica*, *Chaetoceros* spp. (at stations E-1 and E4-W these were mostly *C. decipiens*, at TEW-8 these were mostly *C. criophilus*) and *Pseudo-nitzschia* spp. Cells were analysed in hydrated form within 1 µL of sea water pipetted directly onto the measurement substrate. A compression chamber with IR transparent calcium fluoride windows (0.5 mm thick) was used to hold each sample and prevent the sea water from evaporating prior to measurements being taken (Tobin et al., 2010). The use of the wet chamber meant that differences in the refractive index of the hydrated cells and the measurement medium (seawater) were less than would have been the case for dried cells in air resulting in much less light scattering effects on spectra (Bassan et al., 2009). Spectral data were collected on the Infrared Microspectroscopy Beamline (2BM1B) at the Australian Synchrotron, Melbourne, Australia in July 2013. Spectra were acquired over the measurement range 4000–800 cm\(^{-1}\) with a Vertex 80v FTIR spectrometer (Bruker Optics, Ettlingen, Germany) coupled to an IR microscope (Hyperion 2000, Bruker) fitted with a mercury cadmium telluride detector cooled with liquid nitrogen. The microscope was connected to a computer-controlled microscope stage and placed in a specially designed box purged with dehumidified air. The measurements were performed in transmission via the mapping mode, using an aperture size of 5 µm × 5 µm with a spectral resolution of 8 cm\(^{-1}\), with 64 scans co-added. This aperture size, employed for all species, provided spectra that were unambiguously representative of individual cells (not clumps of cells; Fig. 1). The selected aperture size enabled targeting of the cell interior and avoidance of the cell edge which could cause pronounced light scattering. Additionally, maintaining a consistent aperture size avoided variations in signal to noise ratio throughout the experiment. Although the small aperture size did not cover the entire interior of the cell,
we attempted to overcome heterogeneity across the cell by capturing large numbers of cells (20–50) and varying the measurement position across the cell in a random fashion. The number of co-added scans was chosen as a good compromise between achieving spectra with good signal to noise ratios and the rapid acquisition of data. Spectra were processed using Happ–Genzel appodization and 2 levels of zero-filling. Spectral acquisition and instrument control was performed using Opus 6.5 software (Bruker).

2.3 Multivariate modeling

A multivariate modeling approach was selected for data analysis for two reasons. Firstly spectral data is inherently highly multivariate (containing thousands of variables) and therefore well suited to multivariate analysis. Secondly, the multivariate approach is more robust than univariate methods (such as comparison of peak-height/area ratios) because it detects co-variation across large numbers of variables and is less susceptible to experimental artefacts including baseline effects. SR-FTIR microspectroscopy is a semi-quantitative technique whereby changes in macromolecular absorbance are proportional to changes in the concentrations of those macromolecules. According to the Beer–Lambert Law, absorbance is proportional to the path length through the sample and the concentration of light absorbing molecules, as has been validated for diatoms and other microalgae (Heraud et al., 2007; Jungandreas et al., 2012; Wagner et al., 2010). Given that no independent data was available for the calibration of the SR-FTIR spectral data, we do not report changes in macromolecules in absolute units, however a doubling of absorbance at a particular wavenumber, for example, is indicative of a doubling in concentration of the macromolecules which absorb at those wavenumbers, given adherence to the Beer–Lambert Law. The multivariate modeling approach (including pre-processing methods) described below allows for normalisation of differences in sample thickness, hence changes in the absorbance bands at particular wavenumbers indicate proportional changes in the concentration of the macromolecules associated with those wavenumbers.

7334
SR-FTIR spectral data were exported from the OPUS 6.5 for multivariate analysis using The Unscrambler X v 10.3 (Camo Inc., Oslo, Norway). An initial quality control procedure was performed over the range 3000–950 cm\(^{-1}\). Spectra with maximum absorbance greater than 0.85 (resulting from relatively thick regions of the sample) were excluded from further analyses. The regions 3050–2800, 1770–1730 and 1560–950 cm\(^{-1}\) were selected for analysis since they contain all the major biological bands, but avoided possible issues related to spurious absorbance values for the amide I band region (1730–1560 cm\(^{-1}\)) due to the intense absorbance by water in this region (Vaccari et al., 2012). Firstly, data was smoothed (8 points either side) and second derivate transformed (3rd order polynomial) using the Savitzky–Golay function. Secondly, the Multiplicative Scattering Correction (MSC) function was applied to the dataset for the purposes of reducing any remaining light scattering and to normalize the data.

Data were initially screened for quality using Principal Component Analysis (PCA) to remove obvious outliers, prior to the calculation of average spectra and analysis by Partial Least Squares Discriminant Analysis (PLSDA) (Heraud et al., 2008; Sackett et al., 2013; Wold et al., 2001). Outliers were identified using the Leverage vs. Residual X-variance plots, with a threshold of 5% set nominally. Models were validated using a set of samples not used to build the PLSDA model (i.e. a test set). The calibration and test sets were chosen by randomly assigning two thirds and one third of the samples to each, respectively. The classification accuracy of each model was compared using sensitivity and specificity metrics (Bylesjö et al., 2006).

### 3 Results

#### 3.1 Stations E-1 and E-5 (moderate Fe availability)

Spectra were interpreted based on published literature for band assignments (Table 2). Visual inspection of the average second derivative spectra showed bands characteristic of microalgal samples, with those in the lower region (1250–1000 cm\(^{-1}\)) domi-
nating the spectra (Fig. 2). Differences in the height and position of the peaks indicated that the macromolecular composition varied between taxa. Cell spectra from sites E-1 and E-5 had the strongest absorbance by bands associated with proteins (1540 cm\(^{-1}\)), lipids (3050–2800 cm\(^{-1}\), 1745 cm\(^{-1}\), and 1450 cm\(^{-1}\)), phosphorylated molecules (\(\sim 1240\) cm\(^{-1}\)) and carbohydrates (\(\sim 1150\) cm\(^{-1}\)) compared to stations EW-4 and TEW-8 (Fig. 2a and b). At station E-1 (Fig. 2a), *Pseudo-nitzschia* spp. showed the highest absorbance by proteins and lipids and *E. antarctica* the lowest. Also at station E-1, *F. kerguelensis* cells had the highest absorbance by phosphorylated molecules, followed by *E. antarctica, Pseudo-nitzschia* spp. then *Chaetoceros* spp. At station E-5 (Fig. 2b), *Pseudo-nitzschia* spp. and *F. kerguelensis* cells showed the highest absorbance by proteins and lipids, whereas *E. antarctica* had the lowest. Another notable feature of the cell spectra from station E-5 (Fig. 2c) was the relatively low variability in the region 3050–2800 cm\(^{-1}\), as indicated by small error bars compared to cell spectra from the other stations.

### 3.2 Stations E4-W and TEW-8 (higher Fe availability)

Cells from the stations with higher levels of Fe availability (E4-W and TEW-8) showed spectra with weaker absorbance from bands above 1250 cm\(^{-1}\) compared to those from stations E-1 and E-5 (Fig. 2c and d). As with the other stations, *F. kerguelensis* cell spectra showed the strongest absorbance by phosphorylated molecules (\(\sim 1240\) cm\(^{-1}\)) and the weakest by silicate and carbohydrates (1160–1040 cm\(^{-1}\)) relative to the other taxa.

### 3.3 Multivariate modeling and taxonomic classification

Partial Least Squares Discriminant Analysis (PLSDA) is a multivariate modeling process enabling the modeling and classification of spectral datasets. In this study, PLSDA served to both validate the visual observations made from the average second derivative spectra and to assess the power of SR-FTIR microspectroscopy to taxonomically
classify cell spectra from the mixed, natural diatom communities. PLSDA scores plots showed distinct clustering of cell spectra by taxonomic grouping at all four sites (Fig. 3). PLSDA results supported observations made from average second derivative spectra. For example, interpretation of the scores and corresponding loading weights plots showed strong peaks at \( \sim 1240 \text{ cm}^{-1} \), indicating that \textit{F. kerguelensis} cell spectra had the highest levels of phosphorylated molecules at all four sites. In addition, the PLSDA loading weights plots revealed a consistent anti-correlation between phosphorylated molecules and peaks corresponding to silicate and carbohydrates (bands at \( \sim 1240 \text{ and } 1080 \text{ cm}^{-1} \) had opposite correlation indicated in all four loading weights plots).

Classification of cell spectra by taxon using PLSDA demonstrated a high level of accuracy (Table 3), performing at > 90% specificity and sensitivity for all species at the single cell level. Moreover, cell spectra clustered well by taxonomic group even after pooling the data across the four stations (Fig. 4), indicating that inter-species spectral variability was greater than the environmentally-induced spectral variability.

### 3.4 Community averages compared to individual taxon

Changes in macromolecular composition for the four taxa pooled were compared to those for \textit{F. kerguelensis} alone to see how well community average measurements reflected those of the dominant taxa (Fig. 5). Inspection of the average second derivative spectra (Fig. 5a and d) showed that some trends observed for \textit{F. kerguelensis} were reflected in the bulk averages; however, there were other notable differences in both peak position and intensity. Protein (1540 cm\(^{-1}\)) and phosphorylated molecule (\( \sim 1240 \text{ cm}^{-1} \)) levels were lowest and silicate levels (\( \sim 1080 \text{ cm}^{-1} \)) were highest at site E4-W for both the pooled taxonomic group and for \textit{F. kerguelensis}. Yet, stronger clustering occurred in the scores plots between the high (E4-W and TEW-8) and moderate (E-1 and E-5) Fe stations for \textit{F. kerguelensis} alone than within the pooled taxa. The PLSDA scores plots (Fig. 5b and e) confirmed this observation whereby cell spectra from high Fe stations clustered tightly on the same side of the plot for \textit{F. kerguelensis} but clustering was weaker (but still apparent) in the pooled taxa scores plot. The load-
ing weights plots (Fig. 5c and f) showed similar trends for both the pooled taxon and *F. kerguelensis* with regard to trends in protein, phosphorylated molecules, silicate and carbohydrate levels between sites. In spite of this, the contribution of phosphorylated molecules to variation between cell spectra was stronger for *F. kerguelensis* alone.

The PLSDA by station for *F. kerguelensis* also served to examine the phenotypic plasticity of the species between high and moderate Fe stations (Fig. 5d–f). Models that can robustly discriminate between cell spectra from different stations, should indicate that the macromolecular composition of those cell spectra vary distinctly with station (Sackett et al., 2013). Factors 1 and 3 of the scores plots from PLSDA models explained 49 % of the variation in the spectral dataset, with good clustering by station. *Pseudo-nitzschia* spp. did not show a similar pattern of clustering and model discrimination accuracy was poor (Fig. 6). This indicated that *F. kerguelensis* demonstrated a higher level of phenotypic plasticity under conditions of high and moderate Fe than did *Pseudo-nitzschia* spp.

4 Discussion

The taxon-specific analysis of *F. kerguelensis* cell spectra revealed that stations with lower Fe availability demonstrated higher levels of intraspecific variability. The sources of variation between cell spectra were multivariate, including most of the major macromolecular bands (proteins, phosphorylated molecules, amino acids, silicate and carbohydrates). Differences in variability were not observed when data was pooled across the four taxa, suggesting that community averages may not necessarily reflect the macromolecular composition of *F. kerguelensis*, despite its relatively high abundance within the assemblage. Although studies of intraspecific variability in microalgae are rare, higher levels of population variability have been previously reported for laboratory cultured microalgae under nutrient stress using SR-FTIR microspectroscopy (Héraud et al., 2008). Also, in a previous study of the Southern Ocean diatoms *Fragilariopsis cylindrus*, *Chaetoceros simplex* and *Pseudo-nitzschia subcurvata*, higher intraspecific
variability was shown, particularly for *F. cylindrus*, under extreme salinity and temperature conditions (Sackett et al., 2013). Given that dissolved and particulate Fe levels appeared to be decreasing during the time series stations (indicated by a decrease from E-3 to E-5; Bowie et al., 2014), high intraspecific variability in *F. kerguelensis* could be indicative of a population in transition towards Fe-limitation. Thus, the increased intraspecific variability may have been a sign that the population was in transition, relative to the Fe-enriched stations; however, further studies are required with controlled laboratory trials to confirm that the observed macromolecular changes were due solely to the influence of Fe supply.

Based on the SR-FTIR spectra, levels of silicate were higher in *F. kerguelensis* cells from the Fe-enriched stations (E4-W and TEW-8) compared to the moderate Fe stations (E-1 and E-5). This result contradicts some previous studies which have shown an opposite correlation between Fe availability and silicification (Marchetti and Cassar, 2009), but is not unprecedented. During the SOFeX experiment, Twining et al. (2004a) observed a 16% increase in cellular Si after Fe addition for individual *Fragilariopsis* spp. cells, and Hoffmann et al. (2007) measured an increased ratio of biogenic silica (BSi) to particulate organic phosphate with bulk measurements of Fe-enriched Southern Ocean diatoms during the EIFEX project.

At the Fe-enriched stations (E4-W and TEW-8), the growth rate of the bulk population was substantially elevated compared to the moderate Fe stations (E-1 and E-5; Table 1). In their review of silicon metabolism in diatoms, Martin-Jézéquel et al. (2000) reported that the widely accepted inverse relationship between silicification and growth rate does not always hold, particularly when extracellular silicon is not limiting (Martin-Jézéquel et al., 2000). Thus, it is possible that Fe enrichment, in the presence of adequate ambient Si levels, stimulated both high growth rate and high levels of biogenic silica. In conjunction with silicate, absorbance from phosphorylated molecules and starch was also higher in cell spectra from the moderate-Fe stations (E-1 and E-5; Fig. 2a and b). This is interesting because a previous spectroscopic study found that absorbance from phosphorylated molecules was positively correlated with growth rate (Jebsen...
et al., 2012). Recently however, a proteomics study of acclimation to Fe-limited conditions in the diatom *Thalassiosira pseudonana*, measured substantial up-regulation of proteins related to the pentose phosphate pathway and to amino acid biosynthesis/degradation pathways, including some specifically related to the amino acid tyrosine (Nunn et al., 2013). That study found proteins related to starch and sucrose metabolism (including photosynthesis, oxidative phosphorylation and carbon fixation) that were unique to Fe-limited cultures and can therefore be considered indicative of Fe-limitation. The up-regulation of these proteins is consistent with observations from cell spectra at the moderate Fe stations (E-1 and E-4) of increased absorbance from proteins, tyrosine, and phosphorylated molecules relative to Fe-enriched stations (E4-W and TEW-8). Consistent with the increase in starch levels observed at the moderate-Fe stations, results from laboratory studies using FTIR microspectroscopy to analyse nutrient limited diatom cultures showed suppressed growth and photosynthetic activity was associated with increased starch levels compared to nutrient replete counterparts (Liang et al., 2006).

In the KEOPS2 samples, BSi to particulate organic carbon (POC) ratios for the 20 µm size fraction of the phytoplankton community (which includes the diatoms *F. kerguelensis*, *Chaetoceros* spp. and *E. antarctica*, plus other species of microalgae) were found to be lower at Fe-enriched stations (0.57 and 0.23 at stations E4-W and TEW-8, respectively) and higher at stations with moderate Fe availability (0.63 at stations E-1 and E-5) (Trull et al., 2014). It may seem counter-intuitive that an increase in cellular Si levels could result in a decrease in the BSi/POC ratio; however, looking at the magnitude of difference in BSi and POC between stations shows that BSi increased by a factor of ~ 4.5, whereas POC increased ~ 12 fold at TEW-8 compared to E-1 (Table 1). Thus, the drop in BSi/POC at the Fe enriched station could be explained by increases in both the POC and BSi pools, with the increase in POC being ~ 3 times that of BSi. Although diatoms were the dominant group within the 20 µm size fraction, it should be noted that a decrease in BSi from bulk measurements could have been contributed to by a shift from siliceous diatoms to other, non-siliceous groups. Addition-
ally, samples from the Fe enriched stations were observed to have substantially higher carbon productivity, which could account for increased concentrations of cellular carbon (Jacquet et al., 2014). If the decrease in BSi/POC was caused primarily by a large increase in cellular C concentrations, calculations of cellular C from cell volume may provide underestimates under Fe enrichment, because cell size is constrained by the frustule (Twining et al., 2004a).

Such changes in cellular carbon and Si content are consistent with changes in macromolecular composition observed by SR-FTIR microspectroscopy. The PLSDA loading weights plot for *F. kerguelensis* shows that cell spectra from station TEW-8 had the highest absorbance from silicate (∼1080 cm⁻¹) and carbohydrates (∼1040 cm⁻¹) among the four stations (Fig. 5f). Southern Ocean diatoms have been observed to accumulate carbohydrates to a maximum in the evening, providing a source of carbon skeletons for protein production over night (van Oijen et al., 2004). Given that station TEW-8 was sampled at 10 PM, it is possible that cellular carbohydrate levels were at a maximum at this time. Although carbohydrates contain a relatively lower proportion of carbon (g C (g DW)⁻¹) compared with lipids and proteins (∼0.4, ∼0.76 and ∼0.53 respectively), it is plausible that a substantial increase in carbohydrate storage levels could cause an increase in cellular carbon (Geider and La Roche, 2011). The pattern of changes in silicate and carbohydrate levels between stations was more complex for the pooled data set than for *F. kerguelensis* alone, indicating that community average measurements may not always reflect the composition of the dominant taxa, which can differ widely, and should therefore be interpreted cautiously.

This study and adds to the growing evidence that SR-FTIR microspectroscopy has great value as a tool for quantifying various traits (e.g. growth rate, nutrient status, nutritional value, taxonomic identification) in phytoplankton and other microorganisms (Heraud et al., 2005, 2007; Jebsen et al., 2012; Ngo-Thi et al., 2003; Sackett et al., 2013). Trait-based approaches are a powerful, relatively untapped resource for improving predictions of phytoplankton community composition and dynamics in response to environmental change (Litchman and Klausmeier, 2008). For example, phenotypic
plasticity provides great potential for a species to cope with rapid and prolonged environmental changes (Charmantier et al., 2008). Accurate, taxon-specific models that describe a broad range of phenotypic parameters, referred to here as **phenomic models**, will enhance our ability to predict the response of the phytoplankton community to future climate scenarios. The power of these multivariate phenomic models depends largely on our ability to collect phenotypic data using high-throughput, robust and inexpensive techniques. Multivariate modeling approaches are recognised as integral tools for the analysis of ecophysiological traits (Litchman and Klausmeier, 2008), however less attention has been paid to the power of multivariate *measurement* techniques, such as SR-FTIR microspectroscopy and X-ray Fluorescence Microprobe Analysis, for data collection. Encouraging the use of such multivariate measurement techniques, which can be used to predict multiple traits simultaneously, will dramatically increase the speed of trait data collection for microorganisms. Moreover, the advent of commercially available portable infrared and Raman spectrometers means that spectroscopic measurements can now be made in real time in the field.

5 Conclusions

This study demonstrated the taxon-specific responses of four dominant diatom taxa in association with natural Fe enrichment. These responses were not entirely reflected by the pooled data which was viewed as analogous to bulk community averages. *Fragilariopsis kerguelensis* showed distinct phenotypic differences (i.e. plasticity) between high and moderate Fe stations, whereas *Pseudo-nitzschia* spp. did not (Figs. 5 and 6). Understanding differences between taxa is important for improving our ability to predict phytoplankton community composition and dynamics in response to environmental change (Arrigo, 2005). The current lack of taxon-specific data is related to methodological challenges that limit in situ studies to bulk-community measurements. Methods which permit the analysis of individual cells, such as SR-FTIR microspectroscopy, present a pathway for the collection of taxon-specific data to fill this gap. Such data is in
great demand from carbon cycle and ecosystem modelers, particularly for the Southern Ocean (Carr et al., 2006), and is necessary for advancing our ability to predict the effect of environmental changes, including climate change, on Earth’s marine and terrestrial ecosystems.

Acknowledgements. We thank Stephane Blain (Chief Scientist) and Bernard Queguiner (Voyage Leader) for inviting and supporting L.A.'s and O.S.'s participation in the KEOPS2 programme. The captain of the RV Marion Dufresne II, B. Lassiette, and his crew, and all scientific members of KEOPS2 community are acknowledged. L.A.’s participation in KEOPS2 was supported by an Australian Antarctic Division grant (#3214). This research was undertaken on the infrared microscopy beamline at the Australian Synchrotron, Victoria, Australia with beam-time awarded on the basis of merit, as part of a peer-reviewed provision process. We thank beamline scientists, Mark Tobin and Keith Bamberly, for their assistance with the synchrotron measurements.

Figure 1. Visible images of Chaetoceros spp. (a), F. kerguelensis (b) and E. antarctica (c) cells showing the infrared measurement positions (indicated by cross hairs). The red square around the crosshairs indicates that the aperture size on the infrared microscope was set to 5 × 5 μm.
**Figure 2.** Average second derivative cell spectra from four common genera: *Chaetoceros* spp., *Eucampia antarctica*, *Fragilariopsis kerguelensis* and *Pseudo-nitzschia* spp. Taxonomic abundance varied between stations hence there is no data for *Chaetoceros* spp. and *Eucampia antarctica* at station E4-W, or *Chaetoceros* spp. and *Pseudo-nitzschia* spp. at station TEW-8. (a–d) show four different stations. Peaks show the macromolecular composition of cells which is dominated by phosphorylated molecules (1240 cm\(^{-1}\)), carbohydrates (\(~1150\) cm\(^{-1}\)) and silicate (1080 cm\(^{-1}\)). Peaks found in the spectral region 3050–2800 cm\(^{-1}\), \(~1735\) cm\(^{-1}\) and \(~1450\) cm\(^{-1}\) indicate the presence of lipids. Additionally, peaks at 1540 and 1515 cm\(^{-1}\) indicate the presence of proteins and the amino acid tyrosine, respectively. Error bars indicate one standard deviation from the mean. Note: the y-axis has been reversed to ease examination of the negative peaks (which are the relevant peaks after second derivative transformation).
Figure 3. Taxonomic Classification by PLSDA results for four common genera: *Chaetoceros* spp., *Eucampia antarctica*, *Fragilariopsis kerguelensis* and *Pseudo-nitzschia* spp. (a–h) show four different stations. Scatter plots on the left hand side show scores and line plots on the right hand side show the associated loading weights. The scores plots indicate that the cell spectra cluster well by taxonomic grouping at each site. The loading weights plots indicate that the source of the variation between cell spectra is largely from the lower wavenumber region (∼ 1240–1000 cm⁻¹).
that the source of the variation between cell spectra is largely from the lower wavenumber region (~1240-1000 cm$^{-1}$).

**Figure 4.** Classification of cell spectra by PLSDA with data pooled across stations. PLSDA scores plot (a) shows clustering of cell spectra by taxon. PLSDA Loading weights plot (b) shows spectral bands which drive variation between cell spectra – primarily phosphorylated molecules (1230 cm$^{-1}$), carbohydrates (1150 cm$^{-1}$) and silicate (1080 cm$^{-1}$).
Figure 5. Variations in macromolecular composition for four taxon pooled (a–c) and separately for *F. kerguelensis* (d–f). Average second derivative spectra (a and d) and loading weights plots (c and f) indicate the source of the variation between the taxonomic groups, including strong bands related to phosphorylated molecules, silicate and carbohydrates (~1240–1000 cm\(^{-1}\)). Weaker contributions from lipids and proteins are indicated by the presence of bands at 1730 cm\(^{-1}\) and 1540 cm\(^{-1}\), respectively. Scores plots (b and e) show clustering by station and differences in intrapopulation variability.
Figure 6. Average second derivative spectra (a), PLSDA scores plot (b) and PLSDA loading weights plot for *Pseudo-nitzschia* spp. at stations E-1, E-5 and E4-W. Although the average second derivative spectra show differences between treatments, intra and interspecific variability are both high, resulting in weak clustering by station in the scores plot. The loading weights plot shows that variability between cell spectra is largely driven by protein levels (~1540 cm⁻¹) carbohydrates (1150 cm⁻¹) and silicate (1080 cm⁻¹).
