Abstract

Rivers have been under sampled to establish them as sinks or sources of the atmospheric carbon oxide (CO$_2$). Such poor coverage is well known for tropical and sub-tropical, particularly monsoon driven rivers. An unprecedented high-temporal-resolution (daily) sampling during July 2008–August 2009 were conducted from the Longchuanjiang River of the upper Yangtze basin, a subtropical monsoon river in China to reveal the daily-to-seasonal dynamics of the partial pressure of CO$_2$ ($p$CO$_2$) and CO$_2$ degassing flux from the river. The $p$CO$_2$ levels were supersaturated in CO$_2$ with respect to atmospheric equilibrium (380 µatm) during the entire survey period with obvious daily and seasonal variations, ranging from 450 to 63 000 µatm with an average of 3900 µatm. $p$CO$_2$ values in the surface water in the wet season were relatively low, except flooding period in November, due to a dilution effect by heavy rainfall. However, both daily and monthly minimal and maximal $p$CO$_2$ also occurred in this period. In contrast, the $p$CO$_2$ levels in the dry season were much higher, mainly resulted from lower pH by anthropogenic activities. Net CO$_2$ flux and $p$CO$_2$ were strongly correlated with pH, but weakly with water temperature, dissolved inorganic carbon and water discharge, and uncorrelated with particulate nutrients and biogenic elements. The estimated water-to-air CO$_2$ degassing flux in the Longchuanjiang River was about 110 mol m$^{-2}$ yr$^{-1}$, with the upper limit of 460 mol m$^{-2}$ yr$^{-1}$. Our study also indicated that among the total organic carbon remobilized through soil erosion, around 17 % (11 400 t C yr$^{-1}$) of was emitted to the atmosphere, 52 % (35 000 t C yr$^{-1}$) deposited in the river-reservoirs system and 31 % (21 000 t C yr$^{-1}$) exported further downstream. High spatial and temporal resolution of estimates of CO$_2$ emission from the world large rivers is required due to that catchment characteristics and anthropogenic activities are extremely heterogeneous in space and time.
1 Introduction

Fluvial exports of organic and inorganic carbon to oceans (ca. 1 Pg yr\(^{-1}\)) represent the major biogeochemical role of river systems in the global carbon cycling (Degens et al., 1991; Ludwig et al., 1996). Recent results have demonstrated that concentration of dissolved CO\(_2\) in rivers, lakes and coastal areas is higher than its equilibrium concentration relative to CO\(_2\) in the atmosphere (i.e. 380 µatm), indicating that surface waters are capable of large CO\(_2\) degassing fluxes to the atmosphere (Cole et al. 1994, 2007; St. Louis et al., 2000; Richey et al., 2002; Wang et al., 2007; Bastviken et al., 2011). Amazonian River, for example, 6 times more carbon (470 Tg C yr\(^{-1}\)) by CO\(_2\) evasion than by the sums of riverine TOC (36 Tg C yr\(^{-1}\)) and DIC (35 Tg C yr\(^{-1}\)) were exported (Richey et al., 2002). Carbon emissions as CO\(_2\) from global inland waters to the atmosphere were 1.4 Pg yr\(^{-1}\) (Tranvik et al., 2009), of which, 0.35 Pg C yr\(^{-1}\) from river systems including estuaries (Cole et al., 2007), nearly equivalent to riverine total organic carbon (Ludwig et al., 1996) or dissolved inorganic carbon (DIC) (Gaillardet et al., 1999). CO\(_2\) evasion from rivers to the atmosphere is therefore a significant component of global and regional net carbon budget. Thus, direct measurements of land-atmosphere CO\(_2\) gas exchange without consideration of water-borne fluxes lead to significantly overestimating terrestrial carbon accumulation (Hope et al., 2001). Such a large CO\(_2\) source further compels us to reassess the global carbon budget because freshwater bodies such as lakes, impoundments and rivers are parts of terrestrial landscape, but they have not been included in the terrestrial carbon balance (Battin et al., 2009).

The partial pressure of aqueous carbon dioxide (\(p\)CO\(_2\)) in rivers, reflecting both internal carbon dynamics and upstream terrestrial biogeochemical processes, represents the intensity of gas exchange at the water-to-air interface and demonstrates the source or sink of atmospheric CO\(_2\) for rivers (Richey et al., 2002; Richey, 2003; Yao et al., 2007; S. R. Zhang et al., 2009). The aqueous CO\(_2\) in rivers generally has two sources: (1) allochthonous, i.e. soil CO\(_2\) from mineralization/decomposition of terrestrial organic
matter and root respiration of plants; (2) autochthonous, i.e. CO$_2$ emission from in situ respiration of aqueous organic carbon and photodegradation of dissolved organic matter, as well as CO$_2$ from precipitation of carbonates. Thus, rivers with varying physical characteristics and anthropogenic activities showed large seasonal and spatial heterogeneities in $p$CO$_2$ and thereby water-to-air CO$_2$ flux (Finlay et al., 2009; Guo et al., 2011). As a result, $p$CO$_2$ and over-saturation of dissolved CO$_2$ in rivers could be misestimated if the estimation is conducted using a specific temporal and spatial scale. Environmental changes relative to the terrestrial ecosystem and data paucity especially for most large rivers further result in a large uncertainty (Borges et al., 2005). Hence, high-temporal-resolution sampling needs to be conducted for a better understanding of carbon biogeochemistry in the river systems.

Compared to river systems, estuaries have been well documented, illustrating higher $p$CO$_2$ levels in the European estuaries (Zhai et al., 2007). In China, the previous studies on the Yangtze, the Yellow and the Pearl rivers and their estuaries in particular indicated higher $p$CO$_2$ and thus high carbon emissions (Su et al., 2005; Want et al., 2007; Yao et al., 2007; Zhai et al., 2005, 2007; Zhai and Dai, 2009; L. J. Zhang et al., 2009). Despite many research efforts devoted to the major element geochemistry and associating CO$_2$ consumption in the Yangtze River basin (i.e. Chen et al. 2002; Chetelat et al., 2008; Wu et al., 2008a, b; Li and Zhang, 2008, 2009; Li, S. et al., 2009), little information on CO$_2$ emission is available in its headwater. Though carbon diffusion flux from the entire Yangtze basin has been elucidated recently (i.e. Wang et al., 2007), this estimate using data sets in the Datong station (the lower Yangtze) understandably resulted in large uncertainties due to distinct spatio-temporal discrepancies in water chemistry, nutrient supply and human disturbance in the river basin. Meanwhile, the significance of riverine CO$_2$ outgassing on a global scale needs to be investigated based on regional cases with better seasonal controls. Tropical and sub-tropical river systems are likely to have high respiration and gas transfer velocity of CO$_2$, leading to a poor quantification of carbon emission from inland waters, especially in Asia and Africa where such data are very deficient.
In this paper, we thus chose the Longchuanjiang in the upper Yangtze River, to perform a preliminary investigation on aqueous $p$CO$_2$ through daily sampling within a whole hydrological year. The main objectives of this study are to reveal the daily and seasonal variations of $p$CO$_2$ and examine the mechanism controlling this variability, as well as to estimate water-to-air CO$_2$ flux. Past studies on the Longchuanjiang included major ion geochemistry and chemical weathering, transports and fluxes of nutrients and organic carbon, indicating the great impacts of anthropogenic activities on water quality (Li et al., 2011; Lu et al., 2011a, b).

2 Materials and methods

2.1 Study area

The Longchuanjiang originates near Nanhua County and drains an area of 5560 km$^2$ (24°45’ N–26°15’ N and 100°56’ E–102°02’ E) before joining into the Jinshajiang, a tributary of the upper Yangtze River (Fig. 1). The main channel drains a length of 231 km and the total elevation fall is 2300 m (from 700 to 3000 m a.s.l), respectively. The 1788 km$^2$ upper catchment (upper the Xiaohekou station) has a sub-tropical monsoon climate, characterized by annual mean temperature of 15.6 °C. The average annual precipitation is 825 mm with 86–94 % of the total precipitation occurring in the wet season from May to October. The mean annual runoff and mean annual sediment load at the Xiaohekou Station were $3.2 \times 10^8$ m$^3$ and $4 \times 10^8$ t with pronounced intra-annual and inter-annual variations (Lu, 2005; Li et al., 2011).

The geology of the catchment is composed of low-grade metamorphic rocks, and in particular, clastic rocks (Wu et al, 2008a,b). The area is dominated by purple soil under the Chinese soil classification (Zhu et al., 2007, 2008), which is very susceptible to water erosion and weathering. Erosion was accelerated by growing populations and economic growth, which have contributed to deforestation (in earlier times), intensified agriculture activity, reservoir building, stone excavation and road construction. There
are some small sized reservoirs situated in the drainage basin, resulting in reduction of sediment and organic carbon exports at Xiaohekou hydrological station (Lu et al., 2011b). Also, several counties (Nanhua and Chuxiong) along the riverine network, where industrial and domestic wastes discharge directly, leads to the river polluted by nitrogen (Lu et al., 2011a). Chuxiong County, adjacent to the sampling location, greatly contributes to riverine dissolved solutes (Li et al., 2011).

2.2 Sampling and analyses

Daily precipitation (June 2008–August 2009) and daily discharge (April 2008–March 2009) were recorded by station staff at the Xiaohekou discharge gauging station location in the Chuxiong County (Fig. 1). Daily sampling and field measurements at 08:00 a.m. were conducted from 15 June, 2008 to 31 August, 2009 at the Xiaohekou gauge station. All water samples were collected ~ 0.5 m below the surface water from the central part of the river in acid-washed 5-l high density polyethylene (HDPE) containers. Determination of pH and water temperature \( (T) \) was performed in situ using an Orion 230A pH/Temp meter, which was calibrated before each sampling occasion using pH-7 and pH-10 buffer solutions. Replicate measurements were conducted with a precision of ± 0.04 unit for pH and ± 0.1\(^\circ\) for \( T \), respectively. However, \( T \) and pH from 15 June to 20 July in 2008 were absent. Alkalinity was titrated with two parallel samples using 0.0226 mol l\(^{-1}\) hydrochloric acid on 100 ml of filtrated sample water on the sampling day, the concentrations of alkalinity presented were the averages.

In addition, DIC systems in the September 2007–August 2008 sourced from Li et al. (2011) were adopted for monthly \( p\text{CO}_2 \) calculations.

2.3 DIC species calculations

Total dissolved inorganic carbon (DIC) in river systems is the sum of biocarbonate (\( \text{HCO}_3^- \)), carbonate acid (\( \text{H}_2\text{CO}_3 \)), carbonate (\( \text{CO}_3^{2-} \)) and aqueous \( \text{CO}_2 \) (\( \text{CO}_2\text{aq} \)), and these species are in temperature- and pH-dependant equilibrium with another, such
as the equilibriums between atmosphere CO$_2$ and aqueous CO$_2$, and the dissolved ions caused by CO$_2$. DIC species can be calculated by the Henry’s Law (Stumm and Morgan, 1981):

$$
\text{CO}_2 + \text{H}_2\text{O} \leftrightarrow \text{H}_2\text{CO}_3^* \leftrightarrow \text{H}^+ + \text{HCO}_3^- \leftrightarrow 2\text{H}^+ + \text{CO}_3^{2-}
$$

(1)

$$
K_0 = [\text{H}_2\text{CO}_3^*]/[p\text{CO}_2]
$$

(2)

$$
K_1 = [\text{H}^+][\text{HCO}_3^-]/[\text{H}_2\text{CO}_3^*]
$$

(3)

$$
K_2 = [\text{H}^+][\text{CO}_3^{2-}]/[\text{HCO}_3^-]
$$

(4)

Where, H$_2$CO$_3^*$ is the sum of CO$_2$aq and the true H$_2$CO$_3$. $K$, the Henrys Constant, is temperature dependant dissociation constant in the riverine DIC species and calculated using the following equations:

$$
pK_0 = -7 \times 10^{-5}T^2 + 0.016T + 1.11
$$

(5)

$$
pK_1 = 1.1 \times 10^{-4}T^2 - 0.012T + 6.58
$$

(6)

$$
pK_2 = 9 \times 10^{-5}T^2 - 0.0137T + 10.62
$$

(7)

where $pK = -\log K$.

Thus, the partial pressure of aqueous carbon oxide ($p\text{CO}_2$) can be simply expressed as the following equation:

$$
p\text{CO}_2 = [\text{H}_2\text{CO}_3^*]/K_0 = [\text{H}^+][\text{HCO}_3^-]/K_0K_1
$$

(8)

In the present work, HCO$_3^-$ is considered equaling to alkalinity (i.e. accounting for more than 99% of the total alkalinity) because of the pH values ranging from 6.31–8.51 in the Longchuajiang (Yao et al., 2007).

2.4 Correlating temporal variability

Temporal changes of environmental variables thought to influence river water chemistry, production and CO$_2$ flux were compared to those of net CO$_2$ flux and $p\text{CO}_2$ to
identify potential mechanisms mediating the carbon dynamics, also to evaluate the relative modes of key factors dominating the calculations of net CO\textsubscript{2} flux. In the present study, water conditions (pH, DIC, temperature), nutrient status (DOC, POC, TN, DN, NO\textsubscript{3}\textsuperscript{-}-N, NH\textsubscript{4}\textsuperscript{+}-N, PN, DP, PAP, TP, dissolved Si), and major elements (K\textsuperscript{+}, Na\textsuperscript{+}, Ca\textsuperscript{2+}, Mg\textsuperscript{2+}, Cl\textsuperscript{-}, SO\textsubscript{4}\textsuperscript{2-}) were chosen to quantify their relations with net CO\textsubscript{2} flux and pCO\textsubscript{2}. Major ions and Si were from Li et al. (2011), where twice per month sampling over a two-year period for measurements of \(T\), pH, DIC and major ions. Monthly averages (July 2008–August 2009) of DOC and POC were obtained from Lu et al. (2011b), while averages of nutrients (July 2008–March 2009) from Lu et al. (2011a), and their associations with monthly values of net CO\textsubscript{2} flux and pCO\textsubscript{2} (July 2008–August 2009; Table 1) were determined. Correlation analyses were conducted using Spearman coefficient with the significance at \(p < 0.05\). In addition, stepwise multiple regression was used to identify possible predictor variables for net CO\textsubscript{2} outgassing flux. All the statistical procedures were performed using statistical product and service solution (SPSS) 15.0 for Windows.

### 3 Results

#### 3.1 Hydrological characteristics

The whole hydrological year was relatively wet compared to the mean level in the study area. The annual precipitation (ca. June 2008–May 2009) in the Xiaohekou gauge station was 1000 mm (Fig. 2a), higher than the mean level of annual precipitation during the period from the 1950s to 2000 (825 mm) (cf. Lu, 2005). About 97% of precipitation occurred in the wet season from May to November. The daily mean water discharge was the highest in the beginning of November 2008 (210 m\textsuperscript{3} s\textsuperscript{-1}), the minimum value was in April 2008 (0.12 m\textsuperscript{3} s\textsuperscript{-1}) (Fig. 2b). Total water flow (3.5 \times 10\textsuperscript{8} m\textsuperscript{3} yr\textsuperscript{-1}) was close to the average water discharge of 3.2 \times 10\textsuperscript{8} m\textsuperscript{3} yr\textsuperscript{-1} (cf. Lu, 2005). Water discharge through May to November accounted for 91% of the total water discharge. Sediment...
flux exhibited strong synchrony with water flows and varied from 0 kg s$^{-1}$ to 643 kg s$^{-1}$ (November 2008). It peaked at the beginning of November due to the large storm (Fig. 2b). The sediment transports ($2.7 \times 10^5$ t yr$^{-1}$) was lower than the annual average of $4 \times 10^5$ t yr$^{-1}$ for the period 1970–2001 (cf. Lu, 2005), demonstrating large amounts of sediment trapped behind dams and soil erosion control through vegetation recovery.

3.2 Daily and monthly variations in DIC species

pH ranged from 6.31 to 8.51 with lower values occurred from November to April (Fig. 3). HCO$_3^−$ (alkalinity) varied between 1808 µmol l$^{-1}$ (July 2008) and 4577 µmol l$^{-1}$ (April 2009) (Fig. 3), with a close correlation with water discharge ($\text{HCO}_3^− = 3.69Q^{-0.116}; R^2 = 0.6, p < 0.01; \text{HCO}_3^−$ in mmol l$^{-1}$ and $Q$ in m$^3$ s$^{-1}$). This slight decrease with a drastic increase in water discharge in the flood period was due to the enhanced dissolution of carbonates and detrial calcite as a result of intensified soil erosion during flooding season (Chen et al., 2002; Li et al., 2011).

The partial pressure of surface water CO$_2$ ($p$CO$_2$) showed obvious daily and monthly variations ranging from 451 µatm (August) to 62 712 µatm (November) with an average of 3954 ± 8720 µatm (Fig. 4a). High $p$CO$_2$ indicated the river was characterized by CO$_2$ oversaturation during the entire survey period, being 1.2–165 times the atmospheric $p$CO$_2$ (380 µatm), and more than 80 % of samples had $p$CO$_2$ of 3300 µatm, 9 times the atmosphere level (Fig. 5).

The abnormal high $p$CO$_2$ (62 712 µatm) occurred in the beginning of November 2008, slightly lagging behind the large flooding on the second and third day of November (Figs. 2, 4). This large $p$CO$_2$ values lasted till the initial May (the beginning of the wet season), but $p$CO$_2$ in the February was low (Fig. 4a; Table 1). Despite that one or two values of $p$CO$_2$ in June and July were close or higher than 10 000 µatm, more than 90 % of its values was smaller than 2600 µatm (Fig. 4a). In the remaining wet season, the $p$CO$_2$ were lower, especially from July to September 2008 (Table 1).
Random sampling (i.e. twice per month) indicated $p\text{CO}_2$ ranging from 670 to 12700 µatm with an average of 2600 µatm (Fig. 4b), much lower than the averaged data from daily measurements. This was primarily contributed by samplings in the dry season (Table 1; Fig. 4b). Monthly $p\text{CO}_2$ in July–September 2008, however, was higher than averages from the daily measurements (Table 1; Fig. 4b), demonstrating the necessity of more extensive sampling for CO$_2$ degassing flux.

Daily and monthly variations in $p\text{CO}_2$ and CO$_2$ degassing flux were correlated strongly and inversely with changes in pH ($r = −0.96$ and $−0.99$, $p < 0.001$), and positively with dissolved nitrogen, but only weakly with $T$ ($r = 0.15$, $p < 0.05$), DIC ($r = 0.56$, $p < 0.001$) and Ca$^{2+}$ ($r = 0.29$, $p < 0.05$), but uncorrelated with other chemical parameters such as phosphorus species, silicate, K$^+$, Na$^+$ and Mg$^{2+}$ (Table 2).

4 Discussion

4.1 Controls on aqueous $p\text{CO}_2$

The $p\text{CO}_2$ in the river water is controlled by four major physical and biogenic processes (Richey et al., 2003; Wang et al., 2007; Yao et al., 2007): (1) transport of soil CO$_2$ (i.e. root respiration and decomposition of organic matter) through baseflow and interflow, (2) in situ respiration and decomposition of organic carbon, (3) photosynthesis of aquatic plants, and (4) CO$_2$ evasion from water to air. The first two processes contribute to CO$_2$ and rise in $p\text{CO}_2$, while the last two processes can be responsible for the decline of $p\text{CO}_2$.

The surface water $p\text{CO}_2$ is closely related to soil CO$_2$ content in the drainage basin, and is positively correlated with seasonal variability of temperature and precipitation (Hope et al., 2004). During the wet season, wetted soils by precipitation, proper temperature and high retention times of waters in soils, together with active bacterial activities, produce significant CO$_2$. Aqueous $p\text{CO}_2$ values are also impacted by the intensity of rainfall, hydrological flow path and river discharge, i.e. heavy rain directly flowing into
the stream will dilute the $pCO_2$ in rivers (Finlay, 2003; Hope et al., 2004). On the other hand, biogenic $pCO_2$ uptake and release in the river mediate aqueous $pCO_2$, which is mainly controlled by spatial and seasonal variations in temperature, turbulence and water flow velocity (Barth and Veizer, 1999). All of these above-mentioned physical and biogenic processes contributed to high seasonal variability of $pCO_2$ in the Longchuanjiang (Fig. 4a).

There are enhanced dissolved soil CO$_2$ via baseflow and interflow, in situ increased oxidation of organic matter as a result of both higher temperature and increased organic carbon load during the wet season (9800 vs. 290 t TOC yr$^{-1}$ in the high and low flows, respectively) in the Longchuanjiang (Lu et al., 2011b). Simultaneously, aqueous photosynthesis was at a low level given the highly turbid environment, reflecting by a high suspended solid concentration of 150–450 mg l$^{-1}$ in the high flow condition (Lu et al., 2011b). On the other hand, inactive microbial activities in soils and in situ promoting photosynthesis because of high water clarity in the dry season (Yao et al., 2007). These seem to result in high values of $pCO_2$ in the wet season, such as Ludingjiang and Xijiang in the Pearl River systems (Yao et al., 2007; S. R. Zhang et al., 2009), and other rivers in the world (i.e. Barth et al., 2003). However, the surface $pCO_2$ of our study showed an obvious increase in the dry season and possibly can be due to input of pollutants in the dry season. During the dry season, industrial and domestic wastes from the adjacent county (Chuxiong) caused lower pH values (Figs. 3, 6), resulting in “extra” $pCO_2$ (cf. Duarte et al., 2008; Finlay et al., 2009), while the biogenic processes (i.e. photosynthesis) contributed little to $pCO_2$. However, during the wet season, concentrated rainfall diluted aqueous $pCO_2$, and also the waste waters from the adjacent counties (i.e. Chuxiong) and subsequent pH rise in the Longchuanjiang River, resulting in lower $pCO_2$ levels.

Rains occurred in the beginning of May after a long dry period (Fig. 2). The rainwater penetrated into the soil, coupling with increasing temperature, which promoted bacterial activities in soils and thus resulted in higher water $pCO_2$ level in May 2009 relative to other months during the wet season (cf. Yao et al., 2007). With the constant storms,
rain waters directly entered rivers and thus diluted the aqueous $pCO_2$, resulting in the $pCO_2$ levels in a sequence of May > June > July, and then increased in August 2009 (Table 1). In the later October, little rain occurred and thus abruptly large storm in the beginning (91.3 mm in the first day) of November greatly elevated $pCO_2$ (62 700 µatm) in the Longchuanjiang River (Figs. 2, 4). The consequent largest sediment concentration (Fig. 2) and negligible photosynthesis corroborated $pCO_2$ was dominantly controlled by soil CO2. Then the $pCO_2$ dramatically decreased due to the dilution effect particularly during the second huge flood. The monthly minimum $pCO_2$ of 856 µatm occurred immediately after the heavy storms was a good evidence (Fig. 4a). During this period, biogenic CO2 release and uptake must be small because of the high turbidity and turbulence, fast-velocity flow, and the short residence time of waters.

4.2 CO2 outgassing to the atmosphere

CO2 outgassing from river water to the atmosphere is a function of $pCO_2$ difference between the water and the atmosphere, surface area of water, and the gas exchange coefficient ($D/z$). The diffusion flux of CO2 can be calculated with the following theoretical diffusion model:

$$F = D/z \times (C_{air} - C_{water})$$

Where $F$ is the degassing flux of CO2 between river water and the atmosphere, $D$ is the diffusion coefficient of CO2 in the river, $z$ is the thickness of boundary layer, $C_{air}$ in µatm represents the CO2 concentration in equilibrium with atmosphere, and $C_{water}$ in µatm represents the measured dissolved CO2 concentration in the river waters.

The exchanging rate $D/z$ at the water-to-air interface varies greatly (i.e. 4–115 cm h$^{-1}$) due to several contributing factors, such as river runoff, turbidity, flow velocity, water depth and wind speed (Aucour et al., 1999; Richey et al., 2002; Wang et al., 2007). Considering the annual mean wind speed of 1.7 m s$^{-1}$ and hydrological features in the Longchuanjiang River basin, $D/z$ is estimated to be 8 cm h$^{-1}$ for the calculation of CO2 degassing flux. The similar $D/z$ was also adopted by Wang et al. (2007) for
calculations of CO$_2$ outgassing from the Yangtze basin. We also designated the upper limit value of 15 cm h$^{-1}$ for $D/z$ (Wang et al., 2007; Yao et al., 2007).

Estimate results showed that the Longchuajiang had a CO$_2$ diffusing flux around 111 mol m$^{-2}$ yr$^{-1}$, and the corresponding upper limit was 210 mol m$^{-2}$ yr$^{-1}$. They were obviously higher than that of most world large rivers, but comparable to that of the Xijiang River, and the karst-terrain Maotiao River in the Wujiang (Table 3). When considering average monthly values of $p$CO$_2$ during November–April, and daily $p$CO$_2$ in the rest months of a hydrological year (September 2008–August 2009), CO$_2$ diffusing flux in the Longchuanjiang River was estimated to be 244 mol m$^{-2}$ yr$^{-1}$. The maximal CO$_2$ diffusing flux from the river was calculated up to 460 mol m$^{-2}$ yr$^{-1}$ with an upper limit of $D/z$ (ca. 15 cm h$^{-1}$).

Considering that the water surface area is about 8.6 km$^2$ in the upper Longchuanjiang River (waters accounted for 0.48 % of the total land area; Li, W. et al., 2009b), the upper river will release 9.5 × 10$^8$ mol C yr$^{-1}$ to the atmosphere. Thus, the CO$_2$ degassed from the catchment was close to its fluvial TOC flux (7.1 × 10$^8$ mol C yr$^{-1}$) or DIC flux (7.9 × 10$^8$ mol C yr$^{-1}$) (Lu et al., 2011a). Previous study reported the CO$_2$ degassing flux of 14 mol m$^{-2}$ yr$^{-1}$ in the 1990s from the entire Yangtze basin (Wang et al., 2007), which is only 1/8 of the Longchuanjiang River. Therefore, headwater streams tended to have higher net CO$_2$ flux than the lower basin (Finlay et al., 2009), and previous CO$_2$ emission from the Yangtze basin using the data in the Datong station could be underestimated due to spatio-temporal heterogeneity of catchment characteristics. Similar to the Yangtze, limited spatio-temporal data of dissolved inorganic carbon system in most large rivers is challenging the recent view that carbon emissions from freshwater are much lower than estimated previously (Barros et al., 2011). Our result concluded the upper Yangtze basin undoubtedly is an important net source of atmosphere CO$_2$. 
4.3 Relationships between environmental variables and $pCO_2/CO_2$ flux

Water flows partly contributed to $pCO_2$, as observed by Yao et al. (2007), this could be reflected by our monthly variability of $pCO_2$ and huge fluctuations of $pCO_2$ in the flooding period (i.e. November), however, they showed weak associations ($r = -0.47$, $p < 0.001$; $n = 131$; Figs. 4, 5; Table 3). Yao et al. (2007) ascribed the weak relations between hydrology and $pCO_2$ to insufficient samplings. Our high-temporal-resolution sampling indicated that water discharge was not a good predictor for aqueous $pCO_2$. Nonetheless, the absence of water discharge from April onward in 2009 was a limitation for precisely determining the impacts of hydrology on $pCO_2$.

$pCO_2$ and $CO_2$ degassing flux were more affected by pH than by other physical and chemical parameters on the basis of their correlations, partially because of the high variation in daily pH (6.3–8.5). For example, variation in pH resulted in nearly 10-fold variation in $pCO_2$ than did any other dissolved compounds (DIC, ammonium, nitrate, DIC) or temperature. Our result also demonstrated that temperature variation partially regulated $pCO_2$ levels by altering the alkalinity or DIC concentration, reflecting by the daily and monthly variations of alkalinity content (Fig. 3), as well as observed correlations between $pCO_2$ and DIC ($r = 0.56$, $p < 0.01$). Further investigations into riverine net productivity (Chl-a, plankton, gross primarily production and respiration) should be conducted to quantify their potential roles on net CO$_2$ flux.

Strong predictive relationships between pH and $pCO_2$ and $CO_2$ degassing flux allowed us to identify critical thresholds of the Longchuanjiang River switch from $CO_2$ uptake to gas emitter (Fig. 6). When the pH exceeded 8.7, the river acted as carbon sponges, and when pH dropped below 8.7, the Longchuanjiang River carbon source. Similar findings were also reported in many lake systems (Duarte et al., 2008; Finlay et al., 2009), indicating pH dependence of $CO_2$ flux. This could weaken the relationships between other variables including water discharge and $pCO_2$.

It should be noted worldwide water acidification (Reuss et al., 1987; Sullivan et al., 2005; Ginn et al., 2007; Dual et al., 2011). In the Yangtze River basin specifically the
tributary river of the upper Yangtze River in Southwestern China, sulfate concentrations in river waters increased rapidly and pH declined due to acid deposition and other anthropogenic activities (Chen et al., 2002; Dual et al., 2011). This will exponentially increase carbon emission from river waters. For example, $pCO_2$ in the Longchuanjiang River will increase by three times assuming pH reduction from 8 to 7.5 and ten folds from 8 to 7.

### 4.4 Riverine carbon input and output

There are several fates like burial in sediments, transport to the sea (or downstream), or evasion to the atmosphere for soil carbon reaching freshwaters (Battin et al., 2009; Bastviken et al., 2011), depicting individual inland water such as river system as a combined conduit and reactor for inorganic and organic carbon. However, related observation is rare particularly in the Asian rivers (Tranvik et al., 2009). A carbon budget using the “active pipe” concept by Cole et al. (2007) can be developed to understand the regional and global carbon cycling in the riverine system.

The trap efficiency of sediment around 90% in the upper Yangtze (Lu and Higgitt, 2001) was adopted in our work (Fig. 7a), which was mainly attributed to many reservoirs in the upper catchment. Assuming soil erosion rate was about 1700 t km$^{-2}$ yr$^{-1}$ in the upper Longchuanjiang River, and sediment input from catchment to the river was about $30 \times 10^5$ t yr$^{-1}$, comparable to the observation by Zhou et al. (2004).

Our budget indicated that 67 400 t C yr$^{-1}$ input from the catchment to river, of which inorganic carbon accounted for 33% (22 400 t yr$^{-1}$). Overall, 17% (11 400 t yr$^{-1}$) of the total carbon from catchment released to atmosphere, while 52% (35 000 t yr$^{-1}$) of the carbon was trapped primarily by dams (Fig. 7b). Our estimate was in the range of 1% to 69% of carbon emission as CO$_2$ from land (Tranvik et al., 2009).

Higher concentrations and areal exports of organic carbon in the upper Longchuanjiang catchment (Lu et al., 2011b) could contribute to CO$_2$ evasion. Our results, however, did not show significant relations between CO$_2$ degassing flux and DOC or POC (Table 2). Elevating soil erosion rate by the intensified anthropogenic activities (Zhou...
et al., 2004; Lu, 2005) could increase sediment transport to river system. However, more than 50% of soil carbon was trapped behind dams in the river basin. The deposited carbon would increase the potential of high carbon evasion due to global warming and local climate change.

5 Conclusions

The surface water $p$CO$_2$ was supersaturated with respect to atmospheric CO$_2$ during the whole survey period, averaging about 3954 µatm, thus resulting in a water-to-air interface CO$_2$ outgassing flux of around 100 mol m$^{-2}$ yr$^{-1}$ in the Longchuanjiang River. The aqueous $p$CO$_2$ levels displayed obvious daily and monthly variations due to temporal changes of external biogeochemical processes, in situ biogenic activities and water environment particularly pH by anthropogenic processes. pH was by far the strongest control to $p$CO$_2$ and net CO$_2$ flux that included daily and monthly data, resulting in higher $p$CO$_2$ levels in the dry season. In contrast, the $p$CO$_2$ in the wet season except November showed lower monthly averages, both minima and maxima $p$CO$_2$ occurring in this period. The higher $p$CO$_2$ in the early wet season (May) were mainly contributable to increasing baseflow and interflow flushing soil CO$_2$ into streams. Whereas, the lower $p$CO$_2$ onward (June–October) in the wet season primarily resulted from the diluted effect by precipitation. The Longchuanjiang River in the upper Yangtze basin was a huge carbon source of atmospheric CO$_2$. Water acidification and carbon primarily trapped behind dams also contributed to higher carbon emission. Further study should include potential metabolic controls on CO$_2$ outgassing flux.

The global land carbon sink is estimated to be 2.6 Pg of C per year without consideration of inland waters as a part of terrestrial landscape (Bastviken et al., 2011). Carbon emission from freshwaters thus will greatly counterbalance terrestrial carbon sink. Anthropogenic activities coupled with changing to cascade rivers in the Yangtze River are altering riverine carbon biogeochemical processes, similar to other world large rivers. Moreover, water acidification in most rivers undoubtedly increases CO$_2$ degassing flux.
CO₂ emission from the entire basin estimated using one or two specific sampling stations particularly in the downstream will be under-estimated. Therefore, re-evaluation of CO₂ diffusion flux at the water-to-air interface becomes an increasingly important issue in re-assessing global terrestrial carbon balance.
