Abstract

Increasing atmospheric CO$_2$ is decreasing ocean pH most rapidly in colder regions such as the Arctic. As a component of the EPOCA pelagic mesocosm experiment off Spitzbergen in 2010, we examined the consequences of decreased pH and increased $p$CO$_2$ on the concentrations of dimethylsulphide (DMS). DMS is an important reactant and contributor to aerosol formation and growth in the Arctic troposphere. In the nine mesocosms with initial pH 8.3 to 7.5, equivalent to $p$CO$_2$ of 180 to 1420 µatm, highly significant but inverse responses to acidity (hydrogen ion concentration [H$^+$]) occurred following nutrient addition. Compared to ambient [H$^+$], average concentrations of DMS during the most representative phase of the 30 d experiment were reduced by approximately 60% at the highest [H$^+$] and by 35% at [H$^+$] equivalent to 750 µatm $p$CO$_2$, as predicted for 2100. In contrast, concentrations of dimethylsulphinopropionate (DMSP), the precursor of DMS, were elevated by approximately 50% at the highest [H$^+$] and by 30% at [H$^+$] corresponding to 750 µatm $p$CO$_2$. Measurements of the specific rate of synthesis of DMSP by phytoplankton indicate increased production at high [H$^+$], in parallel to rates of inorganic carbon fixation. The elevated DMSP production at high [H$^+$] was largely a consequence of increased dinoflagellate biomass and in particular, the increased abundance of the species Heterocapsa rotundata. We discuss both phytoplankton and bacterial processes that may explain the reduced ratios of DMS:DMSPt at higher [H$^+$]. The experimental design of eight treatment levels provides comparatively robust empirical relationships of DMS and DMSP concentration, DMSP production and dinoflagellate biomass versus [H$^+$] in Arctic waters.

1 Introduction

Globally, an estimated 18 to 34 × 10$^6$ t of dimethyl sulphide (DMS) are emitted from the oceans to the atmosphere annually (Lana et al., 2011). Although there remains considerable uncertainty associated with this estimate, particularly at higher latitudes, this
is the dominant natural source of sulphur to the atmosphere and plays an important role in atmospheric chemistry. In the troposphere DMS follows a variety of oxidation reaction pathways that influence the fate of other climate active gases, including ozone, methane, ammonia and isoprene (Toumi, 1994; Johnson and Bell, 2008; Chen and Jang, 2012). In addition, oxidation of DMS results in the formation of sulphuric acid ($H_2SO_4$) and methylsulphonic acid (MSA). Sulphuric acid is the primary vapour responsible for atmospheric nucleation, acting as the basis of new Aitken-mode aerosol particles and cloud condensation nuclei (CCN) (Sipila et al., 2010; Kirkby et al., 2011), whilst MSA often makes up a major component of the organic aerosol mass, contributing to the growth of existing aerosols (Rinaldi et al., 2009). The surface energy budget of the Arctic is heavily influenced by cloud formation processes (Curry et al., 1996; Sedlar et al., 2011), which correspondingly play an important role in the melting and freezing of the perennial sea-ice (Kay and Gettelman, 2009). The dominance in summer of small Aitken-mode aerosol particles has been correlated to concentrations of MSA and atmospheric DMS, suggesting a link between the magnitude of DMS emission and cloud albedo over the Arctic (Ferek et al., 1995; Quinn et al., 2002). Although biogenic primary organic aerosols have been proposed as a source of new particles in the Arctic atmosphere (Bigg and Leck, 2008; Orellana et al., 2011), recent direct measurements of particle flux suggest they may make only a minor contribution to aerosol abundance (Held et al., 2011) unless proposed mechanisms of particle fragmentation are substantiated (Karl et al., 2012). Further evidence of the potential importance of DMS to Arctic albedo is provided by a chemical transport model with size-resolved aerosol microphysics which illustrates the substantial contribution of sulphuric acid to formation of CCN during the Arctic summer (Korhonen et al., 2008). Understanding how DMS emissions are likely to alter in the future is therefore particularly important in relation to the rapidly changing Arctic climate.

The Arctic ocean is particularly susceptible to ocean acidification driven by increasing atmospheric $pCO_2$ (Steinacher et al., 2009). The present average surface ocean pH of 8.2 is 0.1 pHunits lower than in pre-industrial times, representing a 30%
increase in the concentration of hydrogen ions \([H^+]\). The largest pH changes worldwide are predicted to occur in Arctic surface waters, where \([H^+]\) may increase by 185\% (\(\Delta pH = -0.45\)) by 2100 (Steinacher et al., 2009). Undersaturation of aragonite, a mineral phase of \(\text{CaCO}_3\), is projected to occur locally in Arctic surface waters within a decade (Steinacher et al., 2009). These levels and speeds of change are likely to impact on the physiology of pelagic organisms, with implications for the composition and function of the pelagic ecosystem (Riebesell and Tortell, 2011).

Evidence that DMS concentrations and hence emissions are likely to alter significantly in response to ocean acidification stem primarily from \([H^+]\) perturbation experiments in natural waters (Wingenter et al., 2007; Vogt et al., 2008; Lee et al., 2009; Hopkins et al., 2010; Kim et al., 2010; Avgoustidi et al., 2012). However, conclusive identification of the mechanisms involved in the altered DMS concentrations is limited, making it difficult to develop predictive models of the effects of ocean acidification on DMS emissions. DMS is a product of the enzymatic cleavage of the S-containing osmolyte, \(\beta\)-dimethylsulphoniopropionate (DMSP), synthesised by a variety of phytoplankton (Reed, 1983; Keller et al., 1989). If ocean acidification results in changes in phytoplankton primary production (Rost et al., 2008; Riebesell and Tortell, 2011) then DMSP production may be altered as a consequence. Changes in primary production may have a considerably larger influence on DMSP production if they are accompanied by taxonomic changes in phytoplankton composition. Intracellular concentrations of DMSP vary from \(<0.1\ \text{mmol}l^{-1}\) to over \(400\ \text{mmol}l^{-1}\) between phytoplankton taxa (Keller et al., 1989). Recent laboratory-based studies found contrasting responses in intracellular DMSP accumulation amongst three phytoplankton taxa exposed to varied levels of \(pCO_2\) (Spielmeyer and Pohnert, 2012), possibly reflecting the variety of physiological functions attributed to DMSP (Nishiguchi and Somero, 1992; Stefels, 2000; Sunda et al., 2002). Phytoplankton DMSP is transformed to the dissolved phase through active exudation, cell autolysis during senescence, viral lysis, and grazing by zooplankton (Stefels et al., 2007). Once in the dissolved phase, pelagic bacteria generally either cleave DMSP generating DMS, or demethylate/demethiolate DMSP.
to methyl-mercaptopropionate, methanethiol or inorganic sulphur (Kiene et al., 2000). In addition, bacterial consumption competes with photochemical transformation as the major loss process for DMS (Vila-Costa et al., 2008; Del Valle et al., 2009). A complex network of enzymatic processes largely dictate DMS concentrations in surface waters (Carpenter et al., 2012) some of which may be prone to alteration in activity in the face of changing [H$^+$]. For instance, bacterial ectoenzyme activities have been shown to be particularly sensitive to changes in [H$^+$] (Piontek et al., 2010), with potential consequences for the bacterial catabolism of DMSP and removal of DMS. Furthermore, uncharacterised algal DMSP lyases, some of which may be extracellular, also show a variety of [H$^+$] optima between species and strains in in vitro assays (Steinke et al., 1998) and may alter activity in relation to changes in environmental [H$^+$].

In light of the pressing need to predict how increasing levels of atmospheric CO$_2$ are going to alter the functioning of the Arctic Ocean ecosystem, we participated in a major mesocosm experiment within the framework of the European Project on Ocean Acidification (EPOCA). Our primary aim was to monitor how the concentration and hence potential emission of DMS responded over time in a series of mesocosms containing natural microbial populations exposed to a range of seawater $p$CO$_2$ and [H$^+$]. We aimed to determine whether alterations in DMS concentration associated with increased ocean acidification were a result of physiological or taxonomic changes in DMSP production. The experimental design of a sequence of mesocosms of increasing acidity that mimicked conditions predicted under increasing atmospheric $p$CO$_2$, allowed us to establish functional relationships relevant to the development of predictive models of DMS emission.
2 Materials and methods

2.1 Location and experimental design

The experiment took place in Arctic waters in Kongsfjorden (78° 56.2′ N; 11° 53.6′ E), on the west coast of Spitzbergen, in the Svalbard Archipelago, during early-mid summer from 31 May (t – 7) to 7 July 2010 (t30). Nine large floating mesocosms ~2 m in diameter and 17 m deep and containing approximately 50 m³, were moored in the fjord within ~100 m of each other offshore from the settlement of Ny-Ålesund. The mesocosm bags were constructed of thermoplastic polyurethane (TPU) and capped, but not sealed, by a polyvinyl chloride (PVC) cover. Both the TPU and PVC transmitted ~95% of the incoming photosynthetically active radiation (PAR). The mesocosms were filled with fjord water screened through 3 mm mesh to eliminate larger organisms. To ensure consistency in the interpretation of results the 7 June was designated as t0.

Seven of the mesocosms received varying amounts of CO₂-saturated seawater over a period of 5 days (t1 to t4), resulting in an initial range of ρCO₂ levels, from ~185 to 1420 µatm. Two control mesocosms received no CO₂ addition, and maintained the initial ambient conditions of the fjord (175–180 µatm) throughout the experiment.

Nitrate, phosphate and silicate were added to all the mesocosms early on t13 in order to stimulate phytoplankton growth. Full details of the experimental setup, evolution of the carbonate systems in the mesocosms and nutrient additions are given in this issue by Riebesell et al. (2012), Bellerby et al. (2012) and Schulz et al. (2012), respectively.

2.2 Quantification of DMS and DMSP concentrations

Water was sampled from each mesocosm using a depth-integrating water sampler (IWS) (Hydrobios, Kiel, Germany). The sampler was programmed to collect a 12 m integrated sample as it was gradually raised through the water column. Samples were generally obtained from all mesocosms between 09:00 and 10:30 LT. Glass-stoppered bottles were gently filled from the sampler in order to avoid air-contact and bubbling.

12808
Samples were transported in a dark cool box back to the laboratory onshore and all were analysed within 2 $\frac{1}{2}$ h of collection. For DMS concentrations, 4 ml samples were gently filtered through a 25 mm GF/F filter and transferred to a purge tower, avoiding any contact with air, and immediately analysed. For total DMSP (DMSPt) concentrations, which includes particulate DMSP (DMSPp) and a minor fraction that comprises dissolved DMSP (DMSPd), 7 ml water samples were fixed using 35 µl of 50 % H$_2$SO$_4$ (Kiene and Slezak, 2006). On return to Plymouth Marine Laboratory, UK, the 7.035 ml samples were hydrolysed for >6 h with a pellet of NaOH to convert DMSP to DMS. One ml of the samples was then carefully transferred to a glass purge tower for extraction of DMS. DMS concentrations were measured using a purge system and cryogenic trap linked to a Varian 3800 gas chromatograph equipped with a pulsed flame photometric detector (PFPD). When triplicate experimental samples were used to test for analytical error, standard deviation was typically <10 % and <10 % of the mean for DMS and DMSPt, respectively. DMS standards for calibration were prepared from DMSP (>98 % purity, Centrum voor Analyse, Spectroscopie and Synthese, Rijksuniversiteit Groningen) in a 1.0 molL$^{-1}$ NaOH solution in Milli-Q water.

### 2.3 DMSP synthesis and production rates

On each experimental date 20 l of water from approximately 6 m depth was collected in 2 $\times$ 10 l acid-cleaned carboys from each of three mesocosms that spanned the range of $p$CO$_2$ concentrations. Trace amounts of NaH$^{13}$CO$_3$, equivalent to ~6 % of in situ dissolved inorganic carbon (DIC), were added to each 10 l volume and following gentle mixing, this was then used to fill 12 $\times$ 1.25 l acid-cleaned polycarbonate incubation bottles for each mesocosm or “$p$CO$_2$ treatment”.

The bottles were incubated at approximately 1 m depth close to the pier at Ny-Ålesund. Photosynthetically active radiation (PAR) at the depth of the incubations averaged 53 % (range 23 to 85 %) of the surface irradiance on the 8 experimental dates and was equivalent to an average depth of 2.3 m (range 0.5 and 9 m) in the mesocosm bags. The 12 bottles provided 4 incubation time points in triplicate for each treatment.
At each time point, 1 l was gravity filtered in the dark onto a 47 mm GF/F filter. Filters were placed in 20 ml crimp-cap vials with 10 ml of 0.5 M NaOH. For storage, samples were frozen at −20 °C.

Determination of de novo DMSP synthesis rates (µDMSP) was carried out according to Stefels et al. (2009). Incorporation of $^{13}$C into DMSP was determined by proton-transfer-reaction mass spectrometry (PTR-MS) of DMS swept from the 20 ml vials and recorded as mass 63, 64 and 65 of protonated forms of $^{12}$C-DMS, $^{13}$C-DMS $^{34}$S-DMS, respectively. The masses from 30 data points, at a 1 s dwell interval, of the peak of the DMS signal were used to calculate the mass ratio of $1 \times ^{13}$C-DMSP ($^{64}$MP) at each point. A weighted average approach that gives most weight to the initial points of the exponentially decreasing DMS peak was used to calculate the mass ratio $^{64}$MP$_t$ for each sample at each time point. The mass ratio progress method described by Stefels et al. (2009) was applied to calculate µDMSP. This applied information from culture-based studies of Emiliania huxleyi to calculate the isotope fractionation factor (Stefels et al., 2009). The exact tracer addition was calculated from the weight of NaH$^{13}$CO$_3$ added and the daily measurements of DIC in the mesocosms. By incorporating shorter time intervals of $\sim$8 h within the $\sim$24 h incubations, uncertainty associated with turnover of the DMSP pool is reduced, ensuring µDMSP measurement represent close to gross synthesis rates.

2.4 Inorganic carbon fixation rates

Primary production was determined from the incorporation of $^{14}$C into particulate and dissolved organic matter as described in Engel et al. (2012). Water samples from the mesocosms were obtained at the same times and integrated depth as those used for the determination of DMS and DMSP concentrations and for the incubations for DMSP synthesis. The polycarbonate bottles used for $^{14}$C-incorporation were incubated at 1 m depth in the vicinity of the mesocosms.
2.5 Variable fluorescence measurements

A fluorescence induction and relaxation (FIRE) fluorometer (Satlantic Inc., Halifax, Nova Scotia, Canada) was used to acquire discrete measurements in dark-adapted samples. Excitation was provided by a high luminosity, blue and green light emitting diode (LED) array (450 and 500 nm peak heights). Filtered (0.2 µm) sample controls (blanks) were analysed at the gain chosen for the measurement on the sample and subtracted from the sample fluorescence sequence at the time of fitting the KPF model. Cell-free controls showed no soluble fluorescence. A detailed description of the protocol used is provided in (Ragni et al., 2008). The retrieved parameter used in the present study is the maximum potential quantum efficiency of Photosystem II ($F_v/F_m$).

2.6 Bacterial production rates

Bacterial protein production was estimated from the uptake of $^{14}$C-leucine that was added to depth-integrated samples from the mesocosms at 40 nmol l$^{-1}$ final concentration. Incubations were terminated by the addition of trichloroacetic acid (TCA) at a final concentration of 5% and processed by the microcentrifuge method. Briefly, samples were centrifuged at 14000 × g to gain a cell pellet that was washed twice with 5% TCA. Incorporation into the TCA-insoluble fraction was measured by liquid scintillation counting after suspension of the cell pellet in scintillation cocktail (Piontek et al., 2012).

2.7 Flow cytometry and group-specific DMSP cell content

Phytoplankton composition and abundance were determined by analysis of fresh samples on a Becton Dickinson FACSort flow cytometer equipped with a 15 mW laser exciting at 488 nm and with a standard filter set up. Samples were analysed at high flow rate (∼70 µl min$^{-1}$), and specific phytoplankton groups were discriminated in bivariate scatter plots by differences in side scatter and red-orange fluorescence (Tarran et al., 2001).
In order to identify the phytoplankton responsible for DMSP production in the mesocosms, fluorescence activated cell sorting was used to determine group-specific intracellular DMSP content (Archer et al., 2011). This was carried out using water sampled from two contrasting mesocosms on two separate occasions towards the end of the experiment (t18 and t21). The same water samples were also size-fractionated using a membrane filter to separate the < 20 and > 20 µm size particles. DMSP concentration was measured in the filtrate and the > 20 DMSP portion calculated by difference.

3 Results

Water initially enclosed within the mesocosms was characteristic of a post-spring bloom environment. In particular, inorganic macronutrient concentrations were diminished (0.12 µmol l⁻¹ of NO₃, 0.7 µmol l⁻¹ NH₄, 0.13 µmol l⁻¹ PO₄ and 0.25 µmol l⁻¹ Si) (Schulz et al., 2012), chlorophyll a concentrations were low (0.21 µg l⁻¹) and the pCO₂ concentration had been reduced to 170 µatm, equivalent to a pH of 8.3 (Bellerby et al., 2012). Correspondingly, DMSP concentrations were low (10 ± 2 nmol l⁻¹) whilst initial DMS concentrations were relatively high (1.5 ± 0.1 nmol l⁻¹); equivalent to a 15 % DMS:DMSP molar ratio. Water temperature gradually increased from an initial 2.0 °C to a maximum of 5.5 °C towards the end of the experiment (Fig. 1). Despite the almost constant daylight, daily average and maximum levels of photosynthetically active radiation (PAR) at the surface varied almost 3-fold but with no clear trend other than a sustained period of lower irradiance at the end of the experiment (Fig. 1). The addition of nutrients on the morning of t13 boosted concentrations to 5.6 µmol l⁻¹ of NO₃, 0.40 µmol l⁻¹ PO₄ and between 1.31 and 1.59 µmol l⁻¹ Si. These concentrations rapidly declined to reach levels as low as the initial conditions by t28.

As environmental conditions changed during the experiment the extent to which the different levels of acidity in the mesocosms influenced biological processes is likely to have altered. Phytoplankton biomass (chlorophyll a) in the mesocosms peaked on three occasions between t4 and t28 (Fig. 1). This pattern defined three distinct phases...
of the experiment (Schulz et al., 2012). In an initial “post-bloom” phase (PI) from t4 to t12, chlorophyll $a$ reached between 1.0 and 1.5 $\mu$g l$^{-1}$ amongst the mesocosms, phytoplankton biomass appeared to be dominated by nanophytoplankton that varied in maximum abundance from 1700 to 5800 cells ml$^{-1}$ and primary production was partially constrained by rates of nutrient remineralisation. A second phase (PII) from t13 to t21 was initiated by the addition of nutrients to non-limiting concentrations that stimulated phytoplankton production; in particular, picoeukaryote populations increased to maximum abundances of 44 to $143 \times 10^3$ cells ml$^{-1}$ between the mesocosms. During PII, chlorophyll $a$ reached maximum values of between 0.7 and 2.1 $\mu$g l$^{-1}$ amongst the mesocosms. As primary productivity was unconstrained by nutrient availability during PII it may be argued that the differences between mesocosms were likely to be principally driven by the varied levels of acidity. Rapidly decreasing inorganic nutrient concentrations and the demise of the picoeukaryote populations marked the start of the third phase (PIII), from t22 to t28; during which diatom and dinoflagellate populations became increasingly dominant and the largest divergence in phytoplankton biomass occurred amongst the mesocosms. During PIII differences between mesocosms possibly reflected a complex combination of nutrient availability, acidity and community succession inherited from PII.

In the present study, hydrogen ion equivalent concentration $[H^+]$ is used as the basis to examine the response to ocean acidification, providing a linear scale against which to compare other parameters, as opposed to pH; and it arguably encapsulates a more pervasive environmental forcing than $pCO_2$ alone. However, $[H^+]$ and $pCO_2$ are directly related in this context.

### 3.1 Patterns of DMS and DMSP temporal progression

To facilitate interpretation of the data and in common with other studies in this issue, the nine mesocosms can be classified into three groups of low, medium and high acidity. Linked broadly to the build-up of chlorophyll $a$, DMSpt concentrations increased during the experiment in all mesocosms, with varied patterns evident in low, medium and...
particularly high acidity treatments (Fig. 2a). The patterns of DMS concentration varied both between levels of acidity and from the patterns of DMSPt progression, particularly amongst the mesocosms of low and medium acidity (Fig. 2b). The peak in DMS concentrations in medium and low acidity treatments during PII and subsequent decline during PIII, contrasts with the gradually accumulating DMSPt. Amongst the high acidity mesocosms the peaks in DMSPt concentrations during PII were not matched by elevated DMS concentrations, which did not reach maximum values until PIII.

Differences in the response of DMSP and DMS concentration to levels of $[\text{H}^+]$ occurred between the three phases of the experiment (Fig. 3). Although average values of DMS and DMSP were lower at high $[\text{H}^+]$ during PI, this did not amount to a significant relationship when the full daily dataset of DMS and DMSP concentrations were tested against $[\text{H}^+]$ by linear regression (Table 1). During PII, DMS and DMSPt show contrasting and highly significant responses to $[\text{H}^+]$ (Fig. 3; Table 1). Compared to ambient $[\text{H}^+]$, average concentrations of DMS during PII were reduced by approximately 60 % at the highest $[\text{H}^+]$ and by 35 % at $[\text{H}^+] = 1.67 \times 10^{-8} \text{ Eq} l^{-1}$, equivalent to 750 µatm $p\text{CO}_2$. In contrast, DMSPt concentrations were elevated by approximately 50 % at the highest $[\text{H}^+]$ and by 30 % at $[\text{H}^+] = 1.67 \times 10^{-8} \text{ Eq} l^{-1}$; corresponding to 750 µatm $p\text{CO}_2$. During PIII average DMS and DMSPt concentrations were again significantly related to $[\text{H}^+]$ but to a lower degree than during PII (Fig. 3; Table 1). Both DMS and DMSPt average concentrations were elevated with increased $[\text{H}^+]$ concentration during PIII. However, particularly in the case of DMS, the high values in mesocosm 9, at the highest $[\text{H}^+]$ concentration, had a disproportionate influence on the significance of the linear regression (Fig. 3).

### 3.2 Synthesis and production of DMSP

In the 6 mesocosms from which measurements were made, specific rates of DMSP synthesis ($\mu$DMSP) decreased during PI from between 0.20 and 0.24 d$^{-1}$, to values of between 0.12 and 0.13 d$^{-1}$, by t12 (Fig. 4). This is equivalent to a decrease in doubling time of the DMSPt standing stocks of from 3 d to approaching 6 d. Following the
addition of nutrients on t13, µDMSP gradually increased amongst the mesocosms during PII and PIII to rates similar to those at the start of the experiment. No consistent relationship between µDMSP and [H+] was apparent amongst the 6 mesocosms over the full duration of the experiment (Fig. 4a).

The determinations of µDMSP rates are based on the change in the mass ratio of 13C-labelled DMS versus the total DMS derived from the molar conversion of particulate DMSP (DMSPp) to DMS by alkaline hydrolysis (see methods). This determination of µDMSP does not require a quantitative measure of DMSPp concentration, simply the isotope ratio. In this study, the estimation of DMSP production uses the routinely measured DMSPt values from the corresponding mesocosms in order to calculate a total DMSPt production rate rather than values of DMSPp. This is done for two reasons: (1) it links µDMSP values to what occurred in the mesocosms and (2) DMSPp concentrations are not required to be accurately determined in the PTR-MS analysis and therefore the use of DMSPt provides a more robust estimate. This approach assumes that the isotope fraction is not different between DMSPt and DMSPp. This is something that could occur if the dissolved DMSP pool contained a different isotope ratio, although in this case the error is likely to be small as the dissolved pool generally makes up only a minor fraction of the total (Kiene and Slezak, 2006). Another potential error is introduced if different pools of DMSPp contain both varied isotope ratio and vary in their susceptibility to cell damage and leakage on filtration. This is of course, also true of many routinely used particulate-based measurements, including a variety of stable- and radiotracer approaches to determine element fixation and production. Despite high µDMSP, initial DMSPt production was low due to the low DMSPt concentrations, averaging 5.2±0.8 (SD) nmol l⁻¹ d⁻¹ in the 6 mesocosms during PI (Fig. 4b). Following nutrient addition and reflecting the higher DMSPt concentrations, DMSPt production increased and became more variable between the mesocosms, rising to an average of 14.0±2.2 (SD) nmol l⁻¹ d⁻¹ by t24 (Fig. 4b). This trend closely resembles the pattern of 14C-based carbon fixation rates (Fig. 4b).
In order to explore the influence of acidity on rates of DMSpt and carbon production, whilst minimising variations imposed by different environmental conditions on each day, values from each experiment were normalised to the rate observed at the lowest [H\(^+\)] on each date. During PII, normalised µDMSP revealed no significant correlation with [H\(^+\)] (Fig. 5a). This lack of positive response in specific synthesis to increased [H\(^+\)] is corroborated by the slight but significant decrease in \(F_v/F_m\) in relation to [H\(^+\)] (Fig. 5d). In contrast, both normalised DMSpt production and \(^{14}\)C fixation increased with [H\(^+\)] to similar proportions (Fig. 5b, c). For DMSpt production this was equivalent to an increase of \(38 \pm 18\) (SD) % at [H\(^+\)] = \(1.67 \times 10^{-8}\) Eql\(^{-1}\); corresponding to 750 µatm \(p\text{CO}_2\); whilst \(^{14}\)C fixation increased by \(43 \pm 14\) (SD) %. Although DMSpt production and \(^{14}\)C-based carbon fixation showed similar relationships to [H\(^+\)], the carbon fixation invested in DMSP by the phytoplankton communities was a minor fraction of the total (<1 %) throughout the experiment.

### 3.3 Taxonomic basis of DMSP production

The difference in DMSpt production with [H\(^+\)] during PII, despite no detectable increase in µDMSP, may reflect alterations in taxonomic composition of the phytoplankton. A change in the proportion of phytoplankton that produced DMSP may be apparent in the ratio of DMSpt to chlorophyll \(a\). However, DMSpt:chl \(a\) was consistently low amongst the mesocosms during all phases, averaging 35 nmol\(\mu\text{g}^{-1}\) during PI (not shown), rising to 50 nmol\(\mu\text{g}^{-1}\) during PII, but with no relationship to [H\(^+\)] (Fig. 6a); and decreasing on average to 38 nmol\(\mu\text{g}^{-1}\) in PIII (not shown). During PIII average DMSpt:chl \(a\) in the mesocosms was significantly \((P < 0.05)\) related to [H\(^+\)], driven to a large extent by decreases at lower [H\(^+\)] (not shown). The low DMSpt:chl \(a\) ratios are consistent with the low proportion of carbon fixation invested in DMSP synthesis.

Although DMSP:chl \(a\) did not vary amongst the mesocosms in PII, specific marker pigments reveal changes in taxonomic composition that may be related to the different DMSpt production. Concentrations of the dinoflagellate-specific pigment peridinin were...
consistently lower than 10 ng l\(^{-1}\) during PI, suggesting that dinoflagellate biomass was low (not shown). However, values increased during PII, and the increased concentrations were significantly related to [H\(^+\)] (Fig. 6b). Considerably higher levels occurred at the highest [H\(^+\)], in mesocosm 9, than in any of the other mesocosms. The important contribution by dinoflagellates to the higher DMSP\(_t\) concentrations at higher [H\(^+\)] during PII is supported by the strong relationship between each for mesocosm 9 (highest [H\(^+\)]) compared to mesocosm 3 (ambient [H\(^+\)]) (Fig. 6c).

Picoeukaryotes were the numerically dominant phytoplankton during PII and showed a significant positive response to [H\(^+\)] (\(y = 16.4x + 38.7\) (P < 0.05); where \(y = \times 10^6\) cells l\(^{-1}\) and \(x = [H^+]\), \(\times 10^8\) equivalents l\(^{-1}\)). Flow cytometric sorting conducted on the last tof PII revealed differences in the DMSP\(_t\) content of picoeukaryote cells, with cells from mesocosm 9 ([H\(^+\)] = 2.42 \(\times 10^8\) equivalents l\(^{-1}\)) having a DMSP content of 0.011(\(\pm\)0.002) pg cell\(^{-1}\) and mesocosm 4 ([H\(^+\)] = 0.83 \(\times 10^8\) equivalents l\(^{-1}\)) cells containing 0.008(\(\pm\)0.003) pg cell\(^{-1}\) (Fig. 7a). When these values are used to calculate the contribution to DMSP\(_t\) at the height of picoeukaryote abundance on t18, they indicate a contribution of between 8 and 14% to the total. The bulk of the remaining DMSP\(_t\) was not accounted for by the flow cytometrically defined nanoeukaryote population or by cells of > 20 \(\mu\)m (Fig. 7b). All three components combined to contribute approximately 13 nmol l\(^{-1}\) in mesocosm 4 and 31 nmol l\(^{-1}\) in mesocosm 9. The latter value is confirmed by the intercept of the regression between peridinin and DMSP for mesocosm 9 during PII (Fig. 6c). Instead, the remaining DMSP\(_t\) is likely to have been contained in cells of < 20 \(\mu\)m that were not included in the nanoeukaryote population that was defined on the flow cytograms. A strong dependence between flow cytometric counts of the dinoflagellate Heterosigma rotundata (~10 \(\mu\)m in length) and DMSP\(_t\) indicates that the increased abundance of this species at higher [H\(^+\)], for instance in mesocosm 5 ([H\(^+\)] = 1.90 \(\times 10^8\) equivalents l\(^{-1}\)) and mesocosm 9 ([H\(^+\)] = 2.42 \(\times 10^8\) equivalents l\(^{-1}\)), was responsible for the differences in DMSP\(_t\) between mesocosms during PII (Fig. 7c). If it is assumed that the temporal differences in DMSP\(_t\) within the mesocosms is due to H. rotundata abundance, then the slope of the
regression provides an estimate of the DMSP content per cell of between 16 and 21 pg DMSP cell\(^{-1}\) (Fig. 7c).

### 3.4 Bacterial production and DMS

The proportion of DMSP\(_t\) converted to DMS is in part, reliant on the yield of DMS from bacterial metabolism of DMSP\(_d\). The dependence of the concentration of DMS on bacterial metabolism was investigated indirectly by comparing bacterial production to the ratio of DMS:DMSP\(_t\). Over the course of the experiment bacterial production determined from the incorporation rate of leucine appeared to be more closely related to the DMS:DMSP\(_t\) ratio at higher [H\(^+\)] than at ambient [H\(^+\)] (Fig. 8). This is reflected in the increasing levels of correlation \(r\) between daily values of DMS:DMSP\(_t\) and bacterial production, with approximately 60% of the variability in DMS:DMSP\(_t\) explained by bacterial production at the highest levels of [H\(^+\)] (Table 2). A significant linear relationship between DMS:DMSP\(_t\) and bacterial production occurred in the three high [H\(^+\)] mesocosms (Table 2); further indicating a greater regulatory role by bacteria on DMS concentration at increased [H\(^+\)].

### 4 Discussion

The DMSP and DMS response during the EPOCA experiment showed broad similarities to mesocosm and shipboard experiments carried out in temperate waters (Table 3). In common with most mesocosm experiments in temperate waters, the addition of nutrients during the EPOCA-mesocosm experiment stimulated phytoplankton production, driving patterns of change in the microbial communities characteristic of seasonal phytoplankton blooms and their succession. Stimulation of autotrophic and heterotrophic production was accompanied by variations in DMS and DMSP concentrations of approximately an order of magnitude; similar to observations of seasonal changes in Arctic waters (Leck and Persson, 1996; Bouillon et al., 2002). During PII of
During the EPOCA experiment, varied [H$^+$] treatments had a more obvious influence on DMSP concentrations, phytoplankton composition and biomass following nutrient addition (PII) compared to the initial nutrient-deplete post-bloom environment (PI). Phytoplankton compositional differences during PIII were driven in part by residual variations in nutrient availability following the different magnitude blooms during PII (Schulz et al., 2012). This made it difficult to confidently assign observed variations in DMSP or DMS responses during PIII to [H$^+$]. During PI (t4 to t12), pigment analyses indicates that the nanoflagellate population that dominated cell abundance, was composed primarily of haptophytes that contributed approximately 50% of the chlorophyll a concentrations (Schulz et al., 2012). The haptophyte group includes species with sufficiently high DMSP cell content, of approximately 1pgDMSP cell$^{-1}$ (Keller et al., 1989), to explain the total DMSPt concentrations observed during PI (Fig. 7d). The lack of a significant difference in DMSPt in relation to [H$^+$] during PI is consistent with observed patterns of nanoflagellate abundance and pigment-based estimates
of haptophyte abundance that also showed no significant differences (Schulz et al., 2012). Haptophytes possess the Type 1 form of RubisCO that has a higher affinity for dissolved aqueous CO$_2$ (CO$_{2aq}$) and as a result, may be less susceptible to direct enhancement of carbon fixation due to increased pCO$_2$ (Reinfelder, 2011). However, they vary markedly in the efficiency of the carbon concentrating mechanism (CCMs) that they employ and this is likely to reflect the extent to which increased pCO$_2$ and hence CO$_{2aq}$ availability enhances productivity (Rost et al., 2008), including DMSP production. In mesocosms in Norwegian coastal waters the specific net growth rates and calcification rates of the coccolithophorid haptophyte *Emiliania huxleyi*, which dominated the phytoplankton, decreased with increased pCO$_2$ (Engel et al., 2005). A similar negative response to raised pCO$_2$ amongst the DMSP-producing phytoplankton may have been responsible for reduced chlorophyll $a$, DMSP and DMS concentrations in the similar experiment at the same location described by Hopkins et al. (2009).

In contrast, during PII (days 13 to 21), raised CO$_{2aq}$ availability appeared to stimulate the net growth of autotrophic picoeukaryotes and dinoflagellates (Fig. 6). Although the DMSP content of picoeukaryotes showed an interesting variation between mesocosms that warrants further investigation, they made only a minor contribution to total DMSPt (Fig. 7). The strong relationship between peridinin and DMSPt concentrations and more specifically between the abundance of the dinoflagellate *Heterocapsa rotundata* and DMSPt (Figs. 6c and 7c), indicates that dinoflagellates were responsible for the bulk (60–70 %) of the DMSP standing stock during PII (Fig. 7c) and for the differences in DMSPt accumulation between levels of [H$^+$]. Autotrophic dinoflagellates possess Type II RubisCO, which has the lowest effective affinity for CO$_{2aq}$ amongst eukaryotic phytoplankton, giving dinoflagellates a disadvantage with respect to carbon fixation in the high-O$_2$, low-CO$_2$ modern ocean (Reinfelder, 2011). Dinoflagellates possess a variety of CCM strategies, including their capacity to indirectly utilize HCO$_3^-$ through acclimation of carbonic anhydrase activity (Rost et al., 2006). Elevated CO$_{2aq}$ availability at high [H$^+$] may have decreased the metabolic costs associated with carbon concentration sufficiently to enable dinoflagellates, and *H. rotundata* in particular, to grow at a higher
rate and produce elevated DMSPt concentrations. Although the authors are aware of no direct measurements of the DMSP cell content of *H. rotundata*, values for closely related species do exist. Intracellular DMSP concentration amongst the genus *Heterocapsa* is typical of dinoflagellates, varying from 190 to 450 mmol l\(^{-1}\) in the four species studied (Keller et al., 1989; Niki et al., 2000; Caruana, 2010). Assuming an average value of 320 mmol l\(^{-1}\) for *H. rotundata* and a cell volume between 130 and 340 µm\(^{3}\) (Olenina et al., 2006) provides an estimated cell content of 6–15 pg DMSP cell\(^{-1}\). A similar value of 16 to 25 pg DMSP cell\(^{-1}\) can be estimated from the regression analyses of DMSPt versus *H. rotundata* abundance in two different mesocosms (Fig. 7c). This confirms the important, but not exclusive, contribution of this species to the [H\(^{+}\)]-related variations in DMSPt.

Several explanations for the reduced DMS concentrations despite increased DMSPt production at elevated [H\(^{+}\)] during PII, can be considered. As stated previously, multiple processes transform phytoplankton DMSP to the dissolved phase including active exudation, cell lysis during senescence, viral lysis and grazing by zooplankton (Stefels et al., 2007). The proportion of DMS produced via these processes is in part a product of the affinity of algal enzymes capable of cleaving DMSP to DMS and acrylate, or DMSP-lyase activity (DLA) (Stefels et al., 1995; Steinke et al., 2002). How algal DLA influences DMS production remains poorly understood but increasingly appears to be an important factor governing seawater DMS concentrations (Archer, 2007; Gali et al., 2011). DLA activity measured in microalgal cell homogenates or in extracellular assays varies considerably between species (Niki et al., 2000; Franklin et al., 2010), and even amongst laboratory isolates of single species (Steinke et al., 1998). No known rates of the DMS-producing capacity of *H. rotundata* are available but separate studies of the DLA activity in the closely related species *Heterocapsa triquetra* provide contrasting evidence of either no detectable capacity (Caruana, 2010) or relatively high DMS-producing potential (Niki et al., 2000). Different laboratory strains and different DLA-assay methods were used in the two studies, possibly explaining the variation. As *H. rotundata* abundance was largely responsible for the increased DMSPt present at
high \( [H^+] \), it is possible that it had low DLA activity compared to other taxa that contributed to the DMSPt pool, partially accounting for the decreased DMS concentrations at high \( [H^+] \).

Production rates of DMS are partly dependent on the turnover of DMSPt. As \( \mu \text{DMSP} \) rates did not vary significantly in relation to \( [H^+] \) (Fig. 5a), the increased DMSPt concentrations at elevated \( [H^+] \) (Fig. 3) must have resulted from reduced loss rates of DMSPt. Based on indirect evidence, Kim et al. (2010) suggested elevated grazing, possibly in response to higher phytoplankton growth rates, may have raised DMS concentrations at higher \( p\text{CO}_2 \) in a mesocosm experiment conducted in Korean waters (Table 1). In contrast, in Arctic waters, grazing or viral lysis of \( H. \text{roundata} \) may have been lower than on the picoeukaryote and nanoflagellate components of the DMSPt pool during PII. If so, this may explain reduced turnover of the total DMSPt pool at higher \( [H^+] \), resulting in reduced transformation of phytoplankton DMSP to the dissolved phase, including DMS production.

Bacterial metabolism may also have contributed to the differences in DMS concentration between levels of \( [H^+] \). Radiolabelled tracer studies have shown that pelagic bacteria generally either cleave DMSP, generating DMS, or demethylate/demethiolate DMSP to methylmercaptopropionate and methanethiol (Kiene et al., 2000). The former provides a 3C-compound for carbon or energy use, whilst the \( \text{CH}_3\text{-S} \) group generated from demethylation may be an energetically efficient route for S-containing protein biosynthesis. The relative magnitude of these catabolic pathways determines the DMS yield from dissolved DMSP consumption, which has been hypothesised to be a product of the sulphur demand of the bacteria (Kiene et al., 2000). Conditions that enhance bacterial production may result in a decreased yield of DMS as the requirement to synthesise S-containing proteins increases the demethylation of DMSP. Variations in bacterial protein production were directly related to differences in primary production amongst the mesocosms during the EPOCA experiment (Piontek et al., 2012). Increased primary production at higher \( [H^+] \), including DMSPt production (Fig. 5), partially stimulated bacterial protein production, potentially generating a greater demand...
for DMSP-sulphur and therefore, a reduced production of DMS. The suggestion of increased DMSP-sulphur demand at high [H$^+$] is supported by the stronger correlations between DMS:DMSPt ratio and bacterial protein production (Table 2).

An additional factor, more difficult to ascertain without direct measurements, is the contribution of bacterial DMS metabolism to decreased DMS concentrations at high [H$^+$] during PII. Bacterial DMS consumption is likely to have been the major DMS removal process in the mesocosms. Photolysis of DMS is primarily driven by UV-wavelengths and therefore would have been minimal in the mesocosms as the walls and covers were UV-opaque. Based on direct measurements of gas transfer velocities in the mesocosms (Czerny et al., 2012), sea-to-air flux of DMS (not shown) averaged a loss of only 2 % d$^{-1}$ of the DMS standing stocks and so had a minimal impact on variations in DMS concentrations. Future ocean acidification studies that combine rate measurements of DMSP and DMS metabolism with the increasing understanding of the genetic basis of DMSP and DMS catabolism (Curson et al., 2011; Reisch et al., 2011), are likely to throw more light on the role of bacteria in regulating DMS concentrations.

To what extent DMS emissions contribute to the optically thin, low lying clouds that are present for approximately 90 % of the time in summer in the Arctic (Curry, 1995), is unclear. Cloud formation in this environment is limited by the availability of cloud condensation nuclei, and is therefore sensitive to alterations in the source strength of aerosol particles (Mauritsen et al., 2011). The small Aitken mode particles that dominate the aerosol composition during summer months are thought to be a product of local sources of primary biogenic and secondary aerosol formation, including H$_2$SO$_4$ derived from DMS emissions; in addition to increased solar radiation that drives the required photochemistry (Korhonen et al., 2008; Orellana et al., 2011). The net effect of low level cloud formation in the Arctic summer is warming at the surface (Intrieri et al., 2002; Mauritsen et al., 2011). If reduced DMS emissions are a widespread consequence of ocean acidification in the Arctic then it may contribute a negative feedback to the general warming. How the magnitude of this effect compares with the
contrasting projected increases in primary biogenic and sea-salt aerosol sources associated with expanding areas of open water in summer months (Held et al., 2011; Kay et al., 2011), constitutes an additional facet of the poorly understood and complex ocean-atmosphere interactions and radiation budgets in the Arctic.

5 Conclusions

Modelling studies vary substantially in predictions of the magnitude of change in DMS emissions from polar waters; suggesting increases in DMS emission of 30 to >150% at the highest latitudes. (Gabric et al., 2005; Kloster et al., 2007; Cameron-Smith et al., 2011). These increases are due to a combination of increased net primary production and regional shifts in community composition that potentially result from sea-ice retreat and changes in temperature, mixing, nutrient availability and light levels. The present study illustrates that alterations in concentration, and hence sea-to-air flux, of DMS due to ocean acidification in the summer in Arctic shelf-seas may be of a comparable magnitude but opposing direction. This emphasises the need to incorporate ocean acidification in future modelling assessments. Moreover, the experimental design of eight treatment levels provides comparatively robust empirical relationships of DMS and DMSP concentration versus [H$^+$]. These are likely to be of value to parameterise or validate DMS-ocean acidification modelling studies.

Clearly, during the most representative phase of the experiment (PII), increased [H$^+$] and corresponding increases in CO$_2$aq availability coincided with increased gross primary production, a component of which was the raised net production of an autotrophic dinoflagellate and elevated DMSP production and standing stocks. Why the increased DMSP production was not transformed into higher DMS concentrations at increased levels of [H$^+$] is less clear. This may have been a function of both reduced algal DMSP-cleavage capacity and increased bacterial demand for DMSP driven by elevated bacterial production associated with the raised primary production at increased [H$^+$]. Understanding how representative the decreases in DMS concentrations observed during
PIL are of ocean acidification-driven changes in the Arctic requires further investigation. Additional experimental studies, aimed at unravelling the ecophysiological factors responsible for changes in the composition of microbial populations that impact on the production and cycling of DMSP and DMS, are now required.

Acknowledgements. This work is a contribution to the European Project on OCEan Acidification (EPOCA), which received funding from the European Community's Seventh Framework Programme (FP7/2007–2013) under grant agreement no. 211384. Additional financial support was provided through the European Centre for Arctic Environmental Research (ARCFAC) (grant number ARCFAC026129-2009-140, awarded to SDA, SAK and FEH) and through Transnational Access funds by the EU project MesoAQUA under grant agreement no. 22822. We gratefully acknowledge the logistical support of Greenpeace International for its assistance with the transport of the mesocosm facility from Kiel to Ny-Ålesund and back to Kiel. We also thank the captains and crews of M/V ESPERANZA of Greenpeace and R/V Viking Explorer of the University Centre in Svalbard (UNIS) for assistance during mesocosm transport and during deployment and recovery in Kongsfjorden. We are grateful to the UK Natural Environmental Research Council for the accommodation and support provided through the NERC-BAS station in Ny-Ålesund. We also thank the staff of the French-German Arctic Research Base at Ny-Ålesund, in particular Marcus Schuhmacher, for on-site logistical support. Finally, we would like to thank Ulf Riebesell, Sebastian Krug and the whole of the Svalbard mesocosm team, who showed great team spirit and comradeship and helped to make the experiment both enjoyable and successful.

$^1$ Time-integrated values over the course of the experiment.

$^2$ Significant differences in DMS concentrations reported from the same study at $P < 0.10$ level (Wingenter et al., 2007).

$^3$ Average concentration during the peak of the phytoplankton bloom.

$^4$ Time-integrated concentrations following nutrient addition (PII); note the values are restricted to the change over $p$CO$_2$ 190 to 750 µatm range, not the full 190 to 1400 µatm range of the experiments.
Fig. 1. Temporal change in environmental variables: (A) surface irradiance (PAR 400–750 nm) and water temperature during the mesocosm experiment. The shaded area spans the range of minimum and maximum irradiance on each day and the dotted grey line represents the daily average value. The dashed line is the average water temperature in the mesocosm bags. (B) The grey shaded area spans the range of chlorophyll \( a \) concentrations measured in the nine mesocosms on each day. The vertical lines show the assigned phases (PI to PIII); nutrient addition occurred on t13.
Fig. 2. Temporal progression of (A) DMSPt concentration and (B) DMS concentration in the three low $p$CO$_2$ mesocosms (initial [H$^+$]: 0.5 to 0.7 × 10$^{-8}$ EqL$^{-1}$; initial $p$CO$_2$: 185 to 270 µmolkg$^{-1}$), three medium $p$CO$_2$ mesocosms (initial [H$^+$]: 0.9 to 1.5 × 10$^{-8}$ EqL$^{-1}$; $p$CO$_2$: 375 to 685 µmolkg$^{-1}$) and three high $p$CO$_2$ mesocosms (initial [H$^+$]: 1.8 to 3.1 × 10$^{-8}$ EqL$^{-1}$; $p$CO$_2$: 820 to 1420 µmolkg$^{-1}$). Bold lines represent the average value and the shaded area illustrates the range for the three mesocosms. In order to illustrate the general patterns of change rather than daily variability, the lines are loess-smoothed fits to the data. The vertical lines mark the division into the three phases.
Fig. 3. Relationships between (A) DMS and (B) DMSP and H\(^+\) concentration ([H\(^+\)]) during each phase (I–III) of the experiment. Values are the mean over the duration of each phase in the nine mesocosms. Error bars show the range. Significant linear regressions based on the full dataset of daily values are shown; details of which are given in Table 1. Note [H\(^+\)] decreases over the duration of the experiment in the mesocosms with higher initial concentration.
Fig. 4. Synthesis and production of DMSP in six mesocosms during the experiment: (A) specific synthesis rate (µDMSP); and (B) production of DMSPt measured over approximately 24 h. The average [H+] for each mesocosm is shown in the legend. The pattern of carbon fixation based on 14C-incorporation over 24 h is shown as minimum and maximum values on each day amongst the nine mesocosms.
Fig. 5. Phytoplankton production in relation to [H\(^+\)] during PII for: (A) µDMSP, measured in water from 3 mesocosms on 3 dates; rates were normalised to the rate measured at the lowest [H\(^+\)] concentration on each date. Error bars show the estimated SD taking into account the precision in DMSP\(_p\) concentrations and the ratio of mass 64\(^-\)DMS; and SD of [H\(^+\)]. (B) normalised DMSP\(_t\) production. Coefficients of the linear regression \((y = a + bx)\) are: \(a = 0.77(\pm0.16 \text{ SE})\); \(b = 0.35(\pm0.10 \text{ SE})\) \((P = 0.011)\) \((n = 9)\). (C) inorganic carbon fixation measured in water from 9 mesocosms on 4 dates during PII. Rates are normalised to the rate measured in mesocosm 3, (initially at ambient [H\(^+\)]). Regression coefficients are: \(a = 0.51(\pm0.12 \text{ SE})\); \(b = 0.39(\pm0.09 \text{ SE})\) \((P = 0.0001)\) \((n = 36)\). Note values measured in mesocosm 7, also at close to ambient [H\(^+\)], were consistently lower than in mesocosm 3. Error bars show the SD of carbon incorporation and of [H\(^+\)]. (D) maximum potential quantum efficiency of Photosystem II \((F_v/F_m)\). The bars represent the SD of individual measurements accounting for uncertainty in estimates of \(F_o\) and \(F_m\). Regression coefficients are: \(a = 0.68(\pm0.01 \text{ SE})\); \(b = -0.016(\pm0.005 \text{ SE})\) \((P = 0.004)\) \((n = 72)\).
Fig. 6. Pigment concentrations in relation to DMSPt and acidification during PII: (A) DMSPt:chl a ratio versus [H\(^+\)]. Values for DMSPt:chl a are the mean during PII in each mesocosm, bars show the range. Values for [H\(^+\)] are the mean ± SD. (B) Peridinin versus [H\(^+\)]. Values for peridinin and [H\(^+\)] are mean ± SD. Coefficients of the linear regression (\(y = a + bx\)) based on the full dataset (\(n = 63\)): \(a = 7.7 (± 2.9\) SE), \(b = 7.3 (± 2.6\) SE); \((P = 0.007)\). Note values from the highest [H\(^+\)] are not included in the regression. (C) DMSPt versus peridinin concentrations in mesocosm 3 (not significant) and mesocosm 9, coefficients of the linear regression: \(a = 34 (± 6\) SE), \(b = 0.44 (± 0.08\) SE); \((P = 0.001)\). The dotted lines show the 95% confident intervals in each case.
Fig. 7. Contributors to DMSP production: (A) differences in the DMSP content of picoeukaryote phytoplankton sorted by flow cytometry collected from mesocosm 4 and mesocosm 9 on t21. Coefficients (±SD) of the linear regression are M4: \(y = 340(±190) + 0.008(±0.003)x\); M9: \(y = 390(±130) + 0.011(±0.002)x\). (B) Components of DMSP during PII on t18 in mesocosm 4 and mesocosm 9 when picoeukaryote abundance was highest; Peuk: picoeukaryote; Nano: nanoeukaryote; >20 µm: component retained by a 20 µm filter. The Peuk component was based on abundance and cell-specific DMSP-content measured on t21; the Nano component was based on abundance and the range of values obtained in North Atlantic waters (Archer et al., 2011). (C) Abundance of Heterocapsa rotundata versus DMSPt concentration in mesocosms 5 and 9 during PII. The fitted regressions are M9: \(y = 2.85(±1.11) + 0.016(±0.003)x\); and M5: \(y = 3.12(±0.90) + 0.021(±0.005)x\). (D) Estimated contribution of nanoeukaryotes (Nano) to DMSP during PI. Values for total DMSP are the mean and range during PI, values for Nano DMSP are based on the mean and range of cell-specific values (0.96(0.5–1.6) pg DMSP cell\(^{-1}\)) measured in North Atlantic waters (Archer et al., 2011). The dotted lines mark the 95% confidence intervals for each linear regression.
**Fig. 8.** Temporal trends in the molar ratio of DMS : DMSPt and bacterial production (BP) measured in mesocosm 3 (close to ambient \([H^+]\)) and mesocosm 9 (highest \([H^+]\)).
