Abstract. With increasing air temperatures and changing precipitation patterns forecast for the Arctic over the coming decades, the thawing of ice-rich permafrost is expected to increasingly alter hydrological conditions by creating mosaics of wetter and drier areas. The objective of this study is to investigate how 10 years of lowered water table depths of wet floodplain ecosystems would affect CO₂ fluxes measured using a closed chamber system, focusing on the role of long-term changes in soil thermal characteristics and vegetation community structure. Drainage diminishes the heat capacity and thermal conductivity of organic soil, leading to warmer soil temperatures in shallow layers during the daytime and colder soil temperatures in deeper layers, resulting in a reduction in thaw depths. These soil temperature changes can intensify growing-season heterotrophic respiration by up to 95 %. With decreased autotrophic respiration due to reduced gross primary production under these dry conditions, the differences in ecosystem respiration rates in the present study were 25 %. We also found that a decade-long drainage installation significantly increased shrub abundance, while decreasing *Eriophorum angustifolium* abundance resulted in *Carex* sp. dominance. These two changes had opposing influences on gross

25 primary production during the growing season: While the increased abundance of shrubs slightly increased gross
primary production, the replacement of *E. angustifolium* by *Carex* sp. significantly decreased it. With the effects
of ecosystem respiration and gross primary production combined, net CO₂ uptake rates varied between the two
years, which can be attributed to *Carex*-dominated plots' sensitivity to climate. However, underlying processes
showed consistent patterns: 10 years of drainage increased soil surface temperatures and replaced *E.*
30 *angustifolium* by *Carex* sp., which increased CO₂ emission and reduced CO₂ uptake rates. During the non-
growing season, drainage resulted in four times more CO₂ emissions, with high sporadic fluxes; these fluxes were
induced by soil temperatures, *E. angustifolium* abundance, and air pressure.

1 Introduction

35 Arctic ecosystems have long acted as carbon sinks due to their consistent low air temperatures and the
presence of permafrost that inhibit the mineralization of soil carbon. Although Arctic net primary production and
standing biomass are smaller than that of adjacent climate zones (Saugier et al., 2001), the low decomposition
rates of Arctic ecosystems have resulted in an accumulation over 1000 Pg of belowground organic carbon in the
upper 3 m of the soil in permafrost regions (Hugelius et al., 2014; Schuur et al., 2015). However, the tendency for
40 Arctic ecosystems to take up more CO₂ on average than they release may be changing due to global climate
change, which has given rise to shifts in air temperature and precipitation patterns. While the photosynthetic rates
and standing biomass in the Arctic have become larger (Epstein et al., 2012; Jia, 2003; Myneni et al., 1997; Xu et
al., 2013), the rate of organic carbon decomposition has also increased (Bond-Lamberty and Thomson, 2010),
which could potentially accelerate CO₂ cycle processes. Further, it is not only a matter of how fast CO₂ circulates
45 between the atmosphere and the upper soil layers, but also what will happen to the massive amount of stored
carbon (Schuur et al., 2009). Thus, understanding how CO₂ flux patterns of Arctic ecosystems change as a

consequence of climate change as well as how this affects the fate of permafrost carbon, is of great importance (Abbott et al., 2016; Koven et al., 2011; Schuur et al., 2008, 2015).

Gross primary production (GPP) is chiefly determined by the length of the growing season (Baptist and
50 Choler, 2008; White et al., 1999; Xia et al., 2015) and leaf area index (LAI; Barr et al., 2004); secondary
influences are water and nutrient availability, as well as local climate conditions such as air temperature and
radiation (Chapin et al., 2012a). As each plant species responds differently to changes in the aforementioned
factors controlling GPP, and as successional changes in vegetation species distribution may take place under a
changing climate, the total amount of carbon assimilated (*net primary production*, NPP) and plant respiration
55 (*autotrophic respiration*, R_a) may undergo changes. The rate of organic matter decomposition (*heterotrophic
respiration*, R_h) increases under warmer and more aerobic conditions, and is also influenced by the quality of
available organic matter. If any of these conditions are modified due to climate change, the rate of R_h may also
change in response.

Warming air temperatures have been observed in the Arctic (Serreze et al., 2000), and disproportionately
60 warmer conditions are forecast in response to climate change (Collins et al., 2013; Kirtman et al., 2013; Overland
et al., 2014). As noted in the preceding paragraph, rates of both photosynthesis and organic matter decomposition
have increased with warmer air temperatures (Belshe et al., 2013; Bond-Lamberty and Thomson, 2010; Epstein et
al., 2012; Jia, 2003; Myneni et al., 1997; Xu et al., 2013), and these trends are predicted to continue. This has the
potential to change Arctic terrestrial ecosystems from a carbon sink to a source, with accelerated organic carbon
65 decomposition as a dominant process (Koven et al., 2011; Schaefer et al., 2011). Schuur et al. (2015) predict that,
under the current climate warming trajectory, ~5 to 15 % of the permafrost carbon pool may be released into the
atmosphere by 2100.

An increase in air temperature can have an immediate impact on soil hydrology, potentially adding complexity to the drivers of CO₂ fluxes and the permafrost carbon pool. In permafrost regions, land surface warming is usually followed by topographical changes, and thus the formation of small-scale local hydrological conditions: Wetter microsites can form due to subsiding ground following permafrost thaw (Jorgenson et al., 2006; O'Donnell et al., 2011), while adjacent areas become drier as water drains laterally to subsided areas. These phenomena are particularly pronounced when increased air temperature thaws ice-rich permafrost, such as ice wedges and ice lenses (Liljedahl et al., 2016). In some Arctic regions, changing precipitation patterns can aggravate or offset this situation. Precipitation in the Arctic has been generally increasing over the last five decades (Kattsov and Walsh, 2000), but patterns are fluctuating across both time and space (Curtis et al., 1998; Stafford et al., 2000); at times, the surface water balance has also been found to be decreasing (Oechel et al., 2000). Although, overall, greater precipitation is expected in the Arctic as the result of intensified hydrological cycles under climate change, the net effect may significantly vary by region (Bintanja and Selten, 2014; Huntington, 2006; Kirtman et al., 2013). Different areas in the Arctic may therefore become either wetter or drier through the combined effects of atmospheric warming and permafrost thaw, as well as varying rates of precipitation.

Several studies have investigated the effects of drainage on CO₂ fluxes in the Arctic (Table 1). Field water table depth (WTD) manipulation experiments and comparison studies with varying WTD have generally shown decreased net CO₂ uptake or increased net CO₂ emission at lower water levels, primarily due to increased ecosystem respiration (R_{eco} ; Christensen et al., 2000; Huemmrich et al., 2010; Kim, 2015; McEwing et al., 2015; Oechel et al., 1998; Olivas et al., 2010; Zona et al., 2011); in most cases, GPP increased as well. Although some studies have shown slightly increased net CO₂ uptake when the increase in GPP is larger than the increase in R_{eco} under drier conditions (Natali et al., 2015), the magnitude of the increase in R_{eco} is usually larger than that of GPP (Christensen et al., 2000; Huemmrich et al., 2010; Kim, 2015; McEwing et al., 2015; Oechel et al., 1998; Olivas

et al., 2010; Zona et al., 2011). The between-site variability of changes in net ecosystem exchange (NEE) presented in Table 1 can be attributed to differences in the observation period, vegetation type, as well as the intensity and duration of WTD changes in the specific studies. Microcosm experiments have also shown inconsistent results, with a decrease in water level resulting in either decreased (Johnson et al., 1996) or increased (Peterson et al., 1984) net CO₂ fluxes. These findings exemplify how the net effect of changes in WTD arise from interactions between multiple factors, and can vary strongly depending on vegetation and soil types (Billings et al., 1982). Therefore, although previous studies have shown that WTD reduction affects GPP and R_{eco} rates, the direction and significance of changes in net CO₂ cycling have been found to differ from ecosystem to ecosystem.

Most of the existing field observation and incubation studies (Table 1) have focused on the short-term effects of changes in WTD, with a few exceptions that included permafrost thaw history (Johnston et al., 2014; Schuur et al., 2009). A further limitation is that most of these studies have been carried out in North America, despite the fact that permafrost regions in Eurasia not only cover about twice the area, but also contain twice the amount of carbon as compared to North America (Tarnocai et al., 2009). Drying manipulation experiments in the Eurasian Arctic with timescales of decades or more will therefore greatly contribute to understanding drainage effects on CO₂ fluxes in Arctic ecosystems. In addition to these growing-season CO₂ fluxes, several studies have highlighted significant contributions of non-growing season CO₂ emissions to the annual CO₂ budget in the Arctic (Coyne and Kelley, 1971; Kelley et al., 1968; Panikov and Dedysh, 2000; Webb et al., 2016; Zimov et al., 1993, 1996). Because of the insulation provided by snow, soil temperatures remain warmer compared to air temperatures, and biological processes may continue throughout the non-growing season (Kelley et al., 1968; Webb et al., 2016; Zimov et al., 1993, 1996). Non-growing-season fluxes are also affected by state changes from water to ice (Mastepanov et al., 2013). However, no studies have yet compared non-growing-season CO₂ fluxes between wet and dry sites.

As a continuation of hydrological manipulation initiated a decade ago in northeastern Siberia (Merbold et al., 2009), the present study investigates how more than 10 years of drainage have affected ecosystem structure and CO₂ fluxes. By directly comparing CO₂ fluxes of a pristine area to those from the drained area, our results go beyond a mere description of the immediate disturbance effects, and clearly point out differences between the properties of pristine and drained ecosystems. These differences highlight how the disturbed area has adapted to persistently drier conditions. Our investigation is focused on shifts in soil temperatures, thaw depths (TD), and vegetation community structure, as well as how these changes then influence net CO₂ exchange and its component fluxes, GPP and R_{eco} (Figure 1). In addition to the growing season, phenomena during the non-growing season will be also described; this represents the first drying manipulation experiment of this nature that extends beyond the growing season.

2 Methodology

2.1 Site description

The study site is located in a Kolyma River floodplain near Chersky, northeastern Siberia (also written as Cherskii or Cherskiy). The dominant vegetation species are tussock-forming *Carex appendiculata* and *lugens*, and *Eriophorum angustifolium*. An organic peat layer (15–20 cm deep) has accumulated on top of alluvial material soils (composed of silty clay), although some organic peat materials can be found within alluvial layers due to cryoturbation.

Based on the record filtered by the Berkeley Earth project (berkeleyearth.org, Station ID 169921) for the period 1960–2013, mean monthly temperatures at the Chersky weather station range between -33 °C in January and +13 °C in July, and the annual mean temperature was -11 °C. World meteorological organization (WMO) records for the period 1950–1999 indicate a total annual precipitation of 197 mm, with about half of this falling as rain in summer. Snowmelt at the site and in the surrounding river basin usually results in a spring flood. This

135 flooding brings an increased water level of up to 50 cm above the soil surface in late May or early June, followed
by a gradual decrease in the water level starting in early July. After the flood waters have receded, the primary
water source is precipitation.

A drainage ring with a ~200 m diameter and minimum depth of 50 cm was constructed in Fall 2004
(Merbold et al., 2009), to drain water into the nearest river channel (Ambolikha). As a result, WTD in this
140 drained area is lowered by 20 cm on average and by up to 30 cm in the growing season compared to control areas
(Merbold et al., 2009). While the spatial range of drainage effects varies by soil topography, high-resolution land
cover classification (Worldview with 2 m resolution; Richards and Xiuping, 1999) has indicated a high
abundance of vegetation groups dominant in dry areas to only within 200 m on both sides of the ditch (Burjack et
al., unpublished data); we can therefore limit the drainage effect to this maximum distance. Starting Summer
145 2013, we measured ecosystem properties and CO₂ fluxes at two sites in parallel (Figure 2): the drained area
affected by the ditch since 2004 (68° 36' 47" N, 161° 20' 29" E), and a control area (68° 37' 00" N, 161° 20' 59"
E) approximately 600 m away from the drained area that is not affected by the drainage ditch. Despite some
short-term diurnal fluctuations of up to a few cm following evapotranspiration, as well as precipitation events and
water supply from thawing permafrost, distinct differences in WTD between these treatment areas persist over
150 the growing season. Each transect of ten plots in the drained and control areas (henceforth referred to as drained
and control transects, respectively) was selected using a stratified systematic sampling method. First, we selected
ten approximate positions with 25 m intervals along the boardwalks or transects; we then selected the final plots
by considering representative vegetation groups of the selected positions, and by selecting specimens small
enough to fit within flux chambers (Table 2, Figure 2). All plots were located within *ca.* 2 m of boardwalks to
155 minimize disturbances.

We conducted three field campaigns. The first was 3 weeks, starting on 20 July 2013 (representing the mid-growing season); the second was 4 weeks, starting on 1 November 2013 (representing the non-growing fall season); and third was 10 weeks, starting on 15 June 2014 (representing the growing season). The non-growing season was defined as the time period when the average daily air temperature was below 0 °C. Although WTD of the drained transect was generally lower by 20 cm than that of the control transect after the spring flood in both years, heterogeneous soil topography rendered varying WTD within each transect: One plot in the drained transect had an average WTD close to that of wet plots in the control transect, and two plots in the control transect had an average WTD close to that of dry plots in the drained transect. Since our objective was to analyze how a decade-long drainage disturbance affects CO₂ fluxes and its links to environmental parameters, we categorized 20 plots into four groups—drained(D)_wet, drained_dry, control(C)_wet, and control_dry—according to transect and WTD category (Table 2). Plots were classified as ‘dry’ when the average WTD of the growing season was lower than -10 cm. In 2013, all 20 plots were observed with equal frequency to investigate spatial variability among plots; in 2014, four core plots (i.e., one plot from each group; Table 2) were more frequently observed to highlight temporal variability over the growing season (Figure 2 & Table 2). Due to different lengths of the observation periods between the two years, we divided data from 2014 into three sub-seasons to distinguish seasonal variability: (2014.1) 15 June–5 July, (2014.2) 6 July–26 July and (2014.3) 27 July–20 August. Sub-season 2014.3 and the 2013 field campaign covered similar periods, based on an analysis of plant phenology with the normalized difference vegetation index (NDVI), and both periods included peak growing season (i.e., when the NDVI of the site was the highest).

2.2 CO₂ flux measurements

At each plot a 60 × 60 cm² polyvinyl chloride (PVC) collar was inserted 15 cm into the ground in late June 2013, three weeks before the first flux measurements. No noticeable plant damage was identified around the

collars after installation, and three weeks was expected to provide enough buffer time for any stabilization needed in the event of minor belowground damage (Högberg et al., 2001; Parkin and Venterea, 2010). To take the flux measurements, a transparent chamber (60 cm on each side, made of 4 mm-thick plexiglass) was placed on the collar. The chamber had an opening valve on the top to avoid pressure effects when we placed the chamber onto the collars. Sensors for air temperature, air humidity, air pressure, and photosynthetically active radiation (PAR) were attached to one side of the chamber and all parameters were measured in parallel with fluxes. These sensors—along with three small fans on a vertical pole attached in one of the corners, for the purpose of mixing the air inside—were placed such that their shadows would not bias incoming solar radiation. CO₂ flux was measured with non-steady-state flow-through (i.e., closed dynamic) method using an Ultra-Portable Greenhouse Gas Analyzer (UGGA, Los Gatos Research, USA), and all data were recorded at 1 Hz with a CR1000 data logger (Campbell, USA).

We restricted each flux measurement to a maximum of two minutes to minimize saturation effects (i.e., warming and pressurized effects) within the chamber. In the event of strong incoming radiation, which can cause temperature to increase more than 1 °C per minute, we placed ice packs on the collar rims inside the chamber to keep temperatures constant while measuring fluxes. The number of ice packs was adjusted by observing the temperature changes at 1 Hz frequency. In addition to measuring NEE using the transparent chamber, in summer we also measured R_{eco} by covering the chamber with a tarp that blocked incoming radiation. In the non-growing season we did not find significant differences between NEE and R_{eco}, probably due to the role of low temperatures, low solar radiation, and snow cover in limiting photosynthesis; we therefore measured NEE only with a transparent chamber.

To calculate the CO₂ flux from the observed changes in CO₂ concentrations ([CO₂]) within the sampling time of two minutes, median values of the [CO₂] slopes were computed selecting multiple time windows based

200 on a bootstrapping approach, and fluxes ($\text{mg C-CO}_2 \text{ m}^{-2} \text{ s}^{-1}$) were calculated by taking into account air temperature, pressure, and the volume and area of the chamber (Rochette and Hutchinson, 2005). Flux rates that fell outside of the range of seasonal mean $\pm 3 \sigma$ (i.e., standard deviation) were removed as outliers. GPP and R_{eco} are expressed in positive values, indicating the amount of CO_2 assimilated and respired, respectively. Negative values for NEE denote net CO_2 uptake by the terrestrial ecosystem, while positive values denote net CO_2 emission to the atmosphere.

2.3 WTD, TD, and soil temperature

WTD was measured during each flux measurement using perforated PVC pipes with a 25 mm diameter, which were installed at each plot. WTD was measured relative to soil surface, with values larger than 0 cm denoting water standing above the soil surface. TD was estimated by pushing a measuring pole into the ground. At every second plot soil temperature probes were installed at 5, 15, 25 and 35 cm (Th3-s, UMS, Germany), and data were recorded while fluxes were measured.

To investigate the effect of soil temperature on R_h , we measured respiration rates of soils at 0–15 cm and 15–30 cm depths by aerobically incubating soils at 15 °C in the laboratory ($N = 6$ for each depth). Respiration rates were corrected for bulk density and average growing-season soil temperatures at each 0–15 cm and 15–30 cm depth of both the wet and dry plots by assuming a Q_{10} value of 2 as the mean for tundra ecosystems (Zhou et al., 2009). The relative heterotrophic respiration rates between the wet and the dry plots were subsequently compared, and were linked to changes in soil temperatures.

2.4 Vegetation community structure

Changes in vegetation community structure between 2003 (before the drainage ditch was installed) and 2013 (nine years after the drainage ditch was installed) were examined using historical data collected in 2003

through the Terrestrial Carbon Observation System Siberia project (TCOS Siberia; Corradi et al., 2005). Vegetation community structure was then identified in 2013 along the same transect as in 2003 (which had not been drained in 2003, but was drained in 2013), as well as in the control transect (newly selected in 2013). Identification was carried out using the same harvest method in all transects. All living vegetation inside a 1×1 225 m^2 quadrat ($N = 4$ per transect) was harvested. Collected vegetation was sorted by species, completely dried at 40°C , and then weighed ($\text{g dry biomass m}^{-2}$). Relative abundance of each species (%) was calculated based on the dry biomass to avoid potential biases linked to the water content of plants.

To correlate abundances of plant species with CO_2 fluxes without destroying plots for further flux observations, we applied a non-destructive point-intercept method using a $60 \times 60 \text{ cm}^2$ quadrat that was divided 230 into $10 \times 10 \text{ cm}^2$ sub-grids in 2014. After creating this grid, we recorded the plant species that a laser pointer hit when pointed downward at each sub-grid intersection, and calculated the percentage of each species' cover. This analysis was performed within each collar, so that vegetation community structure of each plot could be linked directly to CO_2 fluxes. As plots were selected using a stratified method (see Section 2.1), this analysis was also performed at a spot 10 m away from each plot, to confirm that the vegetation community structure of each plot 235 accurately represented the transects.

2.5 Data analysis and interpolation

2.5.1 Interpolation of growing-season CO_2 fluxes

To compare flux variability among plots induced by temporal discrepancies in sampling, and to visualize the implications of these differences for net growing-season CO_2 uptake, CO_2 fluxes for each vegetation and 240 WTD group were interpolated throughout the growing-season observation period. To simulate CO_2 flux rates we

adapted a satellite-data-driven CO₂ flux model, the Polar Vegetation Photosynthesis and Respiration Model (PolarVPRM), which calculates high-latitude NEE by subtracting GPP from R_{eco} (Luus and Lin, 2015):

$$GPP = (\lambda \times T_{scale} \times W_{scale}) \times FAPAR_{PAV} \times \left(\frac{1}{1 + \frac{PAR}{PAR_0}} \right) \times PAR \quad (1)$$

$$T_{scale} = \frac{(T_a - T_{min}) \times (T_a - T_{max})}{(T_a - T_{min}) \times (T_a - T_{max}) - (T_a - T_{opt})^2} \quad (2)$$

$$245 \quad W_{scale} = \frac{a \times WTD}{WTD_{max} - WTD_{min}} + b \quad (0 < a < 1, a + b = 1) \quad (3)$$

where λ is a parameter representing maximum light use efficiency at low light levels, and PAR_0 represents the half-saturation value of PAR. T_{scale} and W_{scale} are scaling variables ranging between 0 and 1 that reflect the influence of air temperature and water availability, respectively, on photosynthesis. The set of three parameters required for calculating T_{scale} , i.e. T_{min} , T_{max} and T_{opt} were set to 0, 40 and 20 °C according to literature
 250 recommendations to avoid the parameter instability that would arise from empirically fitting these parameters, due to the strong positive correlations between T and PAR (Mahadevan et al., 2008). $FAPAR_{PAV}$ is the fraction of PAR absorbed by the vegetation, and is calculated using the Moderate Resolution Imaging Spectroradiometer (MODIS) Enhanced Vegetation Index (EVI).

Site-level meteorological observations of air temperature (T_a) and PAR were used as inputs for
 255 PolarVPRM; these observations were taken from sensors installed in the chamber system (for calibration) and from nearby meteorological towers (for temporal interpolation; Figure 2). The influence of water availability on photosynthesis (W_{scale}) was calculated based on WTD determined next to each plot at the time of flux measurement, with an optimized scaling factor (a, b) to obtain the best fits between $GPP_{modeled}$ and $GPP_{observed}$.

Both parameters (λ and PAR_0) were fitted empirically in R (R Core Team, 2013). PAR_0 was obtained
260 from the curve fit between GPP and PAR measured with flux observations using the nonlinear least squares curve
fitting in R (R Core Team, 2013); λ was calculated as the slope of the linear regression of observed GPP, and of
GPP calculated from Eq. (1). GPP was estimated excluding PAR terms for *CarexEriophorum* in 2013 because no
positive relationship between GPP and PAR was found (see Section 3.3.2). GPP was then computed half-hourly
using linearly interpolated WTD and EVI, as well as half-hourly measured air temperature and PAR from the
265 meteorological station.

R_{eco} was calculated using an empirical Q_{10} model:

$$R_{eco} = \alpha \times e^{k \times T_a} \quad (4)$$

where T_a is air temperature. The two free parameters in this exponential relationship between R_{eco} and air
temperature, α and k , were empirically calculated from chamber-based measurements of R_{eco} and T_a using
270 nonlinear least squares curve fitting in R (R Core Team, 2013). Once these coefficients were calculated, R_{eco} was
calculated at half-hourly intervals with half-hourly-averaged T_a from the meteorological station at each transect.

Parameter optimization and flux interpolation were carried out separately across four core plots for the
year 2014, while 10 plots from each transect were categorized into three vegetation groups and pooled for the
year 2013. These vegetation categories took into account only *Carex* sp., *E. angustifolium*, and shrubs when the
275 relative abundance of each species exceeded 10 % (Table 2). The categorized vegetation groups of the drained
transect were *EriophorumShrub*, *CarexEriophorum* and *Carex*, while those of the control transect were
CarexShrub, *Eriophorum* and *EriophorumShrub* (Table 2). The period of interpolation was restricted to the
observation periods within each year because WTD (W_{scale}) was not measured continuously outside of this period.
The discrepancies between the observed and modeled fluxes were calculated using root mean squared error

280 (RMSE) and mean bias error (MBE). All data points that were used for calibration were utilized for the error estimates due to the limited number of data points.

Uncertainty ranges of the interpolated fluxes were calculated using cross validation by creating 2000 data subsets consisting of randomly selected data points (bootstrapping, 80 % of the total dataset). To obtain an error range of R_{eco} , the 2000 resulting pairs of parameters, and, subsequently, $R_{\text{eco}} \pm 2 \sigma$ were computed for each 1 °C
285 temperature bin. Similarly, 2000 pairs of PAR_0 and λ were estimated for binned PAR. The range of GPP was subsequently estimated by including the rest of the terms from Eq. (1). To constrain the uncertainty ranges of the interpolated fluxes, we took the GPP and R_{eco} error ranges at each point from the corresponding PAR and temperature bin, respectively, that reflected the current condition. Because NEE is calculated as the difference of GPP and R_{eco} , uncertainty ranges were also determined by adding the two error ranges of GPP and R_{eco} . For
290 *CarexEriophorum* and *EriophorumShrub* groups in 2013—for which no positive relationship between GPP and PAR was found or the number of data points was not enough to produce uncertainty ranges, respectively—the bootstrapping step was skipped.

2.5.2 Statistical analysis

Spatial differences in the 2013 WTD and TD between the two transects were tested using an independent
295 *t*-test. A permutational multivariate analysis of variance (PERMANOVA) was performed to compare vegetation community structure between the drained and the control transects of 2013 and 2003. Data from 2014 were not compared with those from 2003 due to the different experimental methods employed. A two-way analysis of covariance (ANCOVA) was carried out with WTD category (wet and dry) and depth as independent variables, to compare soil temperatures between WTD categories. Correlations between WTD and TD were tested by taking
300 values from August of each year when TD was the deepest and the effects of WTD were strongest.

To see if vegetation groups affected the 2013 fluxes, all fluxes were aggregated by vegetation group (see Section 2.5.1; Table 2) and a one-way analysis of variance (ANOVA) was performed for each vegetation group as an independent variable. When independent variables significantly influenced dependent variables, Tukey's post hoc test was applied. To investigate whether vegetation group and soil temperatures significantly affected the non-growing season CO₂ fluxes, one-way ANOVA and multiple linear regressions were performed, respectively. A multiple linear regression analysis was also performed to identify additional major environmental drivers for cold-season CO₂ fluxes. For multiple linear regression analyses, significant variables were defined based on BIC (Bayesian information criteria); with these selected variables the best-fit regression models were identified, based on the AIC (Akaike information criterion). All statistical analyses were performed using R (R Core Team, 2013).

3 Results and discussion

3.1 WTD changes from drainage

Following flooding due to snowmelt in early June, the drainage ditch effectively lowered WTD in the drained transect. Average differences in WTD between the two transects were significant with a mean drop of approximately 20 cm, and a maximum difference of up to 30 cm during a three-week period in Summer 2013 (independent *t*-test, $P < 0.001$, $t = -4.55$, $df = 17.91$; Figure 3a). Approximately the same difference in mean WTD was observed in the middle of the 2014 growing season. However, several significant rainfall events from late July of 2014 triggered an increase in WTD in the dry plots, especially in the drained transect (Figure 3b). The amount of precipitation was similar at both transects, but WTD for some drained_dry plots was more susceptible to increases in WTD compared to the control_dry plots; this was because the width of the area within the drainage ring was three times larger than that of the elevated areas of control_dry plots. In addition, drainage may slow when the water level rises within the drainage ditch due to the obstruction of water flow by taller

vegetation—*E. angustifolium* and aquatic plants—at the end of the growing season (Allan, 1995; Green, 2005). As a result, WTD in drained_dry plots stayed high longer than in the control transect following heavy rainfalls. Similar patterns were also observed in 2005, one year after the drainage ditch was installed (Merbold et al., 2009). Nonetheless, WTD difference between the wet and the dry plots showed distinct patterns. In the long term, it can be speculated that new drainage pathways will be established, which will lead water away more effectively after precipitation events, and thus reduce the fluctuations in WTD we observed at our site. Transferring our findings to a natural disturbance (e.g., the formation of a connected system of troughs following ice-rich permafrost thaw), we expect that water drainage will be more effective than our drainage manipulation, as thawing permafrost following persistently warmer conditions will induce more pronounced topographical changes (Jorgenson et al., 2006; Liljedahl et al., 2016; O'Donnell et al., 2011).

3.2 Shifts in soil temperature and TD and their effects on CO₂ fluxes

3.2.1 Soil temperature and TD

Our two-way ANCOVA indicated that drainage resulted in both stronger diurnal fluctuations in soil temperatures at shallow layers and colder soil temperatures at deep layers, as compared to the wet plots (Table 3 & Figure 4). This finding highlights the important role of water content in the thermal properties of organic soils, with the soil of shallow layers of the drained transect tending to heat up more easily during the daytime in the dry plots due to the reduced heat capacity of dry organic soil (Abu-Hamdeh, 2003; Idso et al., 1975; Lakshmi et al., 2003; Reginato et al., 1976). At the same time, these dry organic soils also have lower thermal conductivity, limiting downward heat transfer; as a result, deeper layers remained colder than soil at the same depth in the wet plots (Abu-Hamdeh, 2003). This mechanism reduced TD in the dry plots, the effect of which became more distinct at the end of the growing season due to the continued effects of WTD (Figure 5). The positive

345 correlations between WTD and TD in August clearly show this trend (for 2013: $r = 0.47$, $P < 0.05$, for 2014: $r = 0.67$, $P < 0.001$).

3.2.2 Soil temperature and TD effects on CO₂ fluxes

GPP and R_{eco} rates increased with soil surface temperatures (Figure 6) because warmer soil temperatures generally accelerate both photosynthesis (Lawrence and Oechel, 1983; Schwarz et al., 1997) and root respiration (Boone et al., 1998). The average R_{eco} rates of the dry plots were 25 % higher than those of the wet plots in 2013 (independent *t*-test, $P < 0.001$, $t = -5.70$, $df = 532$) despite the fact that GPP rates were found to be lower in the dry plots, meaning that lower R_a rates would have been expected (Figure 6). This increase in the R_{eco} rates can be partly explained by the increased rates of R_h under more aerobic conditions following drainage: As anaerobic respiration is slower and less efficient than aerobic respiration, carbon release from both organic and mineral soils (surface and deep soil layers, respectively) under aerobic conditions can be 4–10 times higher than under anaerobic conditions (Lee et al., 2012). However, drier conditions altered soil temperature regimes, and these effects further affected R_h rates.

Modifications in soil surface temperatures had greater impacts on R_h than those in deep soil temperatures: The warmer soil surface temperatures of the dry plots increased R_h by 240 %, while colder deep soil temperatures reduced R_h only marginally as compared to the wet plots. Combining these two contrasting effects, R_h rates in dry plots were elevated by 95 % as a result of the stronger effects of the soil surface temperatures as compared to deep soil temperatures on compacted peat soils. This increase was largely due to a greater amount of organic carbon—an increased total carbon content by 11 % as well as more compacted soil with an increase in bulk density by 44 % (data not shown)—in the dry plots affected by warmer temperatures at surface layers. Contrary to the accelerated respiration rates at the surface, colder deep soil temperatures and reduced thaw depths imply that carbon currently stored in permafrost can be preserved following drainage. In addition to these contrasting

effects, another opposing influence of the physical structures of vegetation on soil temperatures—for example, the negative relationship between shrub abundance and TD due to shade (Blok et al., 2010) and the positive relationship between shrub abundance and TD due to decreased albedo (Bonfils et al., 2012)—with continuously changing vegetation communities following drainage (see Section 3.3) need to be monitored over a longer period
370 of time to gain further insight into the net impact of secondary drainage on carbon accumulation and CO₂ fluxes.

3.3 Shifts in vegetation community structure and its effects on CO₂ fluxes

3.3.1 Vegetation community structure

In its natural, undisturbed state, the vegetation community of this floodplain has historically been dominated by *Eriophorum angustifolium*, followed by *Carex appendiculata* and *lugens*. This vegetation
375 community structure was reflected in the observations made in 2003 (Corradi et al., 2005)—that is, before the drainage ditch was constructed (Figure 7, top panel)—as well as in the control transect in 2013 (Figure 7, center panel). After a decade of drainage, the abundance of *E. angustifolium* decreased, while shrubs (*Betula exilis*, and *Salix fuscescens* and *pulchra*) and *Carex* sp. became the dominant species in the drained transect (Figure 7, lower panel). While no statistically significant differences were found between the vegetation community structures in
380 2003 and in the control transect of 2013 (PERMANOVA, $F = 1.62$, $P = 0.19$), significant differences were found between both the 2003 and the drained transect of 2013 (PERMANOVA, $F = 3.31$, $P < 0.05$) and between the two transects of 2013 (PERMANOVA, $F = 5.22$, $P < 0.05$). Although we did not experimentally compare the two observation methods (see Section 2.4), a qualitative comparison of results from 2013 (i.e., harvest) and 2014 (i.e., point intercept) showed a similar abundance of each species; this implies that these two different methods can be
385 used to compare vegetation community structures.

In the control transect the vegetation community structures of the wet and the dry plots were dominated by *E. angustifolium* and *Carex* sp., respectively, but some dry plots within the drained transect showed a

vegetation transition stage (Table 2). Plots in the drained transect that were categorized as *CarexEriophorum* (Table 2) showed a mixture of young *Carex* sp. (without discrete tussock forms or small developing tussocks) and short and thin *E. angustifolium*. The presence of this mixture implies that these areas were formerly dominated by *E. angustifolium*, which is abundant in saturated areas, but whose abundance decreased due to drainage. The core plots that were selected based on drainage manipulation and WTD category represented this vegetation shift well; control_wet and drained_wet were dominated by *E. angustifolium*, control_dry was dominated by *Carex* sp. and shrubs and drained_dry showed a transition stage from *E. angustifolium* to *Carex* sp. (Table 2).

We underestimated the abundance of shrubs (*Betula* and *Salix* sp.) within the collars in the drained transect as a result of the methodological choice to exclude tall shrubs when selecting plots to ensure that all of the vegetation could fit into the chambers when measuring fluxes (Note that these results are presented to compare CO₂ fluxes by vegetation group, see Section 2.4). The abundance of shrubs within the collars of the drained transect was 2 % on average, while independently investigated average abundance along the transect was 20 % on average. This discrepancy will be taken into account in the following sections when interpreting the effects of shrubs on CO₂ fluxes.

3.3.2 Vegetation effects on CO₂ fluxes

Chamber-based CO₂ flux measurements during the 2013 growing season showed similar mean and standard deviations of NEE, GPP, and R_{eco} rates between the two transects (Figure 8). However, fluxes showed a large variability across plots within each transect (each of which was *ca.* 225 m), which results from one-way ANOVA indicated to be closely linked to the dominant vegetation groups (NEE: $F = 24.99$, $P < 0.001$; Figure 8a). R_{eco} also differed by dominant vegetation group, but this difference was not as pronounced as it was for GPP (GPP: $F = 11.23$, $P < 0.001$, R_{eco}: $F = 3.63$, $P < 0.01$; Figure 8b & 8c).

410 One of the vegetation effects on CO₂ fluxes was that, *Eriophorum*-dominated plots in both transects had higher rates of photosynthetic uptake than *Carex*-dominated plots. GPP rates of *Eriophorum*Shrub were 55 % higher than those of *Carex* in the drained transect, and those of *Eriophorum*Shrub and *Eriophorum* were 20 % higher than those of *Carex*Shrub in the control transect in 2013 (Figure 8b). In 2014, conversely, GPP rates of *Carex*Shrub were 5 % higher than those of *Eriophorum*Shrub in the control transect, but this difference was

415 insignificant (Table 4). Thus, the decrease in *E. angustifolium* as a result of drainage generally reduced carbon accumulation in the terrestrial ecosystem. *Carex**Eriophorum* plots in the drained transect—which represent undergoing a vegetation transition from *E. angustifolium* to *Carex* sp. following drainage—showed the lowest GPP rates in both years, despite the presence of *E. angustifolium* (Figure 8b). In this transition stage (which is here characterized by declining *E. angustifolium*) or in early succession stages, plants assimilate less CO₂ than

420 they previously did due to lower biomass, and can be more susceptible to disturbances (Chapin et al., 2012b; Niinemets, 2010). The dry and warm year of 2013 was an especially good example of this process: These plots showed slightly decreased GPP rates along with increasing PAR (Supplementary Figure S1), implying that the combination of high PAR and high air temperature caused water stress to plants. Under the same climate conditions, *Carex*Shrub in the control transect—which can be considered to be the potential vegetation

425 communities of *Carex**Eriophorum* groups—took up significantly less CO₂ than in 2014, but did not show decreasing GPP rates (Supplementary Figure S1). This implies that when *E. angustifolium* is fully replaced by *Carex* sp. and shrubs, the current *Carex**Eriophorum* plots may not undergo water stress as easily as they currently do although they can be still strongly influenced by climate. Taking into account such transition effects after 10 years of drainage is important given that the fraction of these areas of the total area—three out of ten plots—is

430 not small. Moreover, this finding highlights the fact that ecosystem adaptation to new environmental conditions may take a long time, as 10 years was evidently not sufficient for this ecosystem to be resistant to disturbances, e.g., harsh climate conditions.

Increasing shrub abundance slightly compensated for lowered GPP rates in drained areas following a reduction in *E. angustifolium* coverage. *Eriophorum*Shrub of the control transect, which had 10 % shrub coverage, had, on average, 4 % higher GPP rates than *Eriophorum* in 2013 although this difference was not significant (Figure 8b). This difference is expected to be larger if the abundance of shrubs was not underestimated (see Section 3.3.1). Also, this compensation may become larger with increasing abundance and biomass of shrubs following continuing drainage. Increasing the abundance of shrubs not only changes carbon exchange rates between the atmosphere and the terrestrial ecosystem, but also carbon storage patterns within the terrestrial ecosystem (Shaver and Jonasson, 2001). In the drained transect, living aboveground biomass—the sum of leaf and stem—was larger than in the control transect, and in 2003, while the biomass of green leaves decreased, that of stems increased, mostly due to the increased abundance of shrub species (Supplementary Figure S2). When shrubs continue to expand, a large portion of carbon will be stored in plants, especially in shrubs' stems, and the proportion of litter added to the soil will decrease accordingly (Supplementary Figure S2). The subsequent effects of these changes, such as litter quantity and quality added to soils and its decomposability (Hobbie, 2008; Schädel et al., 2014), need to be further investigated to better understand long-term vegetation effects on CO₂ fluxes.

3.4 Growing-season CO₂ fluxes

3.4.1 Gap-filled growing-season CO₂ fluxes

The modeled fluxes for both 2013 and 2014 had similar patterns to the observed fluxes: *Eriophorum*-dominated plots (i.e., wet plots) generally showed higher GPP rates than *Carex*-dominated plots (i.e., dry plots) in both transects (Table 4). In addition, the 10 % difference in shrub cover between *Eriophorum* and *Eriophorum*Shrub from the control transect did not significantly affect GPP rates (Table 4). R_{eco} rates were consistently greater in the dry plots, in part due to increased R_h rates, and the cumulative R_{eco} increased with

455 drainage by 5 % in 2013 and by 10 % in 2014 (Table 4). Combining the effects of vegetation and soil
temperatures on GPP and R_{eco} rates, the net effects of drainage on CO_2 fluxes (NEE) was $-0.3 \text{ g C-CO}_2 \text{ m}^{-2} \text{ day}^{-1}$
(i.e., 25 % more CO_2 uptake) in 2013 and $+0.98 \text{ g C-CO}_2 \text{ m}^{-2} \text{ day}^{-1}$ (i.e., 35 % less CO_2 uptake) in 2014 when
460 daily CO_2 fluxes of 20 days, weighted by the number of plots of each group, were compared (Table 4). This range
was comparable to other drainage studies presented in Table 1. However, the net CO_2 flux changes were in
opposite directions in these two years due to the control_dry (CarexShrub) plots' sensitivity to dry and warm
conditions during the 2013 observation periods (see Section 3.3.2), as well as pooling the wet and the dry plots to
compare changes in flux rates for transect level. Despite the variability between years for transect level, patterns
of underlying processes were consistent: After 10 years of drying manipulation, the replacement of *E.*
angustifolium by *Carex* sp., more aerobic conditions, and increased soil surface temperature all weakened CO_2
465 uptake and increased CO_2 emission (Table 4).

3.4.2 Model error from interpolation

Comparing observed against modeled flux rates for all individual measurements in the database, the
mean RMSE of R_{eco} was 0.009 and 0.007 $\text{mg C-CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ for 2013 and 2014, respectively, and that of GPP was
0.021 and 0.016 $\text{mg C-CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ for 2013 and 2014, respectively (Supplementary Table 1). Low uncertainty
470 ranges imply that variations in R_{eco} and GPP can be mainly explained by air temperature and PAR, respectively.
The uncertainty ranges of R_{eco} were large compared to those of GPP (Supplementary Table 1), suggesting that
 R_{eco} rates varied with factors other than air temperature, while GPP rates mostly varied with PAR. Larger RMSE
and MBE in the drained transect in 2013 compared to the control transect can be attributed to the pooling of data
points by vegetation group, as well as to the limited number of data points; the large error in GPP for the Carex
475 group of the drained transect can be attributed to varying standing biomass, and that of the EriophorumShrub in
the drained transect stems from the small number of data points (Supplementary Table 1). In 2014, data points for

each group came from only a single plot, but varying WTD and thickening thaw depth over the growing season resulted in relatively large errors (Supplementary Table 1).

3.5 Non-growing-season CO₂ fluxes

480 Due to the low air temperatures and weak solar radiation, GPP in the non-growing season was negligible. Although a limited amount of photosynthetic activity could have theoretically taken place during this time (Atanasiu, 1971), no significant differences were found between NEE and R_{eco}, implying that CO₂ fluxes consisted mostly of CO₂ released from the soil. The drained transect emitted an average of four times more CO₂ than the control transect: If the observed flux pattern is representative for the entire month of November, the net
485 CO₂ emission of this month would be 11 g C-CO₂ m⁻² in the drained transect and 3 g C-CO₂ m⁻² in the control transect.

Some plots in the drained transect showed sporadically high fluxes, the rates of which were comparable to R_{eco} rates from the growing season (Figure 9). These high fluxes in the drained transect could be linked to vegetation groups, especially the abundance of *E. angustifolium*, as well as to air pressure and soil temperatures
490 (multiple linear regression, adj. $R^2 = 0.46$, $P < 0.001$; pressure, $P < 0.001$; T_{soil} at 5 cm, $P < 0.001$; *Eriophorum*, $P < 0.001$; pressure × T_{soil} at 5 cm, $P < 0.001$; pressure × *Eriophorum*, $P < 0.001$). This may be a part of the physical processes outlined by Mastepanov et al. (2008, 2013), through which the freezing of soil pushes stored
495 CO₂ and CH₄ gases in soil to the atmosphere through cracks in soil or dead plant bodies. Although soil temperatures between 0–35 cm were consistently below zero, soil temperatures at 35 cm did not fall below -5 °C until the end of November. Ongoing freezing at greater depths than 35 cm and low air pressure could have stimulated CO₂ emission from the soil to the atmosphere through dead *E. angustifolium*. The fact that the CO₂ fluxes were influenced by soil temperatures implies that high CO₂ emissions were not exclusively triggered by the physical expression of existing CO₂ in soils, but also from ongoing respiration at relatively mild soil

temperatures insulated by snow (Kelley et al., 1968; Webb et al., 2016; Zimov et al., 1993, 1996). CO₂ fluxes in
500 the control transect were also influenced by the abundance of *E. angustifolium*, air pressure, and soil temperatures
(multiple linear regression, adj. $R^2 = 0.21$, $P < 0.001$; Tsoil at 5 cm, $P < 0.01$; Tsoil at 15 cm, $P < 0.01$; Tsoil at
25 cm, $P < 0.01$; *Eriophorum*, $P < 0.05$; Tsoil at 5 cm \times *Eriophorum*, $P < 0.001$; Tsoil at 15 cm \times *Eriophorum*, P
 < 0.001 ; Tsoil at 25 cm \times *Eriophorum*, $P < 0.001$), but the rates were relatively constant over time and without
high sporadic fluxes, unlike in the drained transect (Figure 9).

505 Although the CO₂ fluxes in the non-growing season were partially explained by vegetation group, air
pressure, and soil temperatures, the amount of variation (R^2) together explained by these factors was low. We also
cannot firmly conclude that the observed sporadic high CO₂ fluxes in November were largely driven by these
factors, because we did not observe CO₂ fluxes continuously along with soil temperatures; what's more, these
high CO₂ fluxes were only observed in the drained transect despite there being similar conditions in the control
510 transect. High uncertainties and limitations in predicting both non-growing-season CO₂ fluxes and possible high
CO₂ fluxes during the thawing season (Friborg et al., 1997) need to be addressed to determine the net effects of
drainage on the annual CO₂ fluxes of this site. Nevertheless, the observed considerably higher CO₂ fluxes in the
non-growing season for the drained transect imply that drainage not only affects growing-season CO₂ fluxes, but
also has the potential to alter non-growing-season fluxes significantly.

515 **5 Conclusion and final remarks**

Drainage of a floodplain near Chersky resulted in an average WTD drop of 20 cm. This substantially
altered both biogeophysical and biogeochemical ecosystem properties over the span of a decade, with profound
net impacts on CO₂ fluxes. The first change important for CO₂ processes was that vegetation community structure
in drained areas shifted significantly toward increased *Carex* sp. and shrub species (*Betula* and *Salix* sp.) and
520 decreased *E. angustifolium*. The second change was that WTD variation led to divergent soil temperature profiles

by depth, with drained areas showing greater fluctuations in soil surface temperatures due to their low heat capacity, and with deeper soil demonstrating colder temperatures due to the low thermal conductivity of the dry soil above it. Consequently, the drained areas had shallower thaw depths compared to the control areas.

525 These aboveground and belowground changes significantly affected CO₂ fluxes. The drained areas showed higher R_{eco} due to more aerobic conditions, with a greater amount of organic carbon affected by warmer soil surface temperatures. Dominant plant species in the drained areas took up less CO₂ (i.e., *Carex* sp. engaged in less GPP) than *E. angustifolium*, which is dominant in the control wet areas. Increased abundance of shrubs slightly compensated for the decrease in GPP, but, in our datasets, it could not fully balance out the losses. Overall, drainage increased net CO₂ uptake (NEE) by 25 % in 2013 but decreased it by 35 % in 2014 during the 530 20 days of the growing season when the two transects were compared. The opposite patterns of the two years can be attributed to the control_low plots, which showed large variations with climate. Despite the inter-annual variability, both years had consistent trends toward the replacement of *E. angustifolium* with *Carex* sp., more aerobic conditions, and increased soil surface temperature, all of which weakened net CO₂ uptake (NEE). In the non-growing season, CO₂ emission was four times larger in the drained than in the control areas, partially as a 535 result of the abundance of *E. angustifolium*, air pressure, and soil temperatures.

Ecosystem changes after 10 years of drainage in an Arctic floodplain decreased CO₂ uptake and increased CO₂ emissions in both the growing and non-growing seasons. These findings highlight the importance of considering the changes in ecosystem properties under persistent dry conditions when investigating CO₂ fluxes in response to global climate changes. As ongoing global warming thaws ice-rich permafrost and makes some 540 regions drier, Arctic wetlands may accumulate less carbon in the terrestrial ecosystem, respire more CO₂ from shallow soil layers, and preserve carbon in deep soil layers. Given that vegetation communities continue changing after 10 years, with different areas then responding differently to climates, further observations of this

site, as well as of other ecosystems in the Arctic, are needed over a longer term to better predict the fate of the Arctic in the face of global climate changes.

800

805 Table 1 CO₂ flux changes (g C-CO₂ m⁻² day⁻¹) in response to a water table depth (WTD) decrease, expressed as either flux_{control} – flux_{lower-WTD} or flux_{higher-WTD} – flux_{lower-WTD}. Negative net CO₂ flux rates represent a net increase in terrestrial CO₂ uptake; positive changes denote a decrease in net CO₂ uptake by the terrestrial ecosystem or an increase in terrestrial CO₂ emissions to the atmosphere. The ranges of these changes are from different years, soil types, and study sites. Numbers in parentheses represent percent change compared to the original (control, WTD condition) flux.

Sites	WTD change	Net CO ₂ flux change	Reference
Coastal plain	Drawdown	+ 0.59 (+160 %)	Huemmrich et al. (2010)
	3 cm lower	+ 0.23 (+87 %)	Olivas et al. (2010) ¹
	Up to 3.6 cm lower ⁶	+ 1.17 (+63 %)	Christensen et al. (2000) ²
	7–7.5cm lower	+ 0.36 to 0.4 (+450 % to 500 %)	Oechel et al. (1998)
	8.5 cm lower	+ 2.99 (+365 %)	Kim (2015) ³
	11.9 cm lower ⁶	+ 0.41 (+67 %)	Zona et al. (2011) ³
	20 cm lower ⁶	+ 0.72 (+37 %)	McEwing et al. (2015)
Floodplain	20–35 cm lower	- 0.06 (-47 %)	Merbold et al. (2009) ⁴
Moist tundra	2.5 cm lower	- 0.02 (-3 %)	Natali et al. (2015) ⁵
Laboratory	Saturated	- 2.63 to - 1.41	Johnson et al. (1996)

vs. field capacity	(-1716 to -344 %)	
5 cm lower	- 0.61 to + 0.96	Billings et al. (1982)
	(-59 to +72 %)	
10 cm lower	+ 2.21 (+184 %)	Peterson et al. (1984)

¹ Only data from 2008 were used, as this was the only time when the WTD of the drained area was lower than
810 that of the control area.

² Only from grassland data.

³ Only ecosystem respiration was considered (no gross primary production).

⁴ Only data from 2003 and 2005 were used, as these were the only years when climate conditions were similar.

⁵ Only data from 2013 were used, as this was the only time when the WTD of the drained area was lower than
815 that of the control area.

⁶ WTD difference from natural variation instead of manipulation.

820 Table 2 Water table depth (WTD) and vegetation characteristics of plots. Average WTD was calculated by pooling all WTD measurements from both years by each vegetation group (mean \pm standard deviation), except the period where the whole area was flooded from snowmelt. When the average WTD of the growing season was larger than -10 cm, plots were classified as wet group. Vegetation groups were created by taking into account only *Carex* sp., *E. angustifolium*, and shrubs when the relative abundance of each species exceeded 10 %. The relative abundances of consisting plant species (mean \pm standard deviation) are separately presented.

Transect	Plot Number	ID	WTD group	Group abbr.	Average WTD (cm)	Vegetation group	Vegetation abundance (%)
Drained	0		Wet	Drained_wet	4.6 \pm 2.2	EriophorumShrub	90, 10
	1, 2, 4		Dry	Drained_dry	-14.1 \pm 8.4	CarexEriophorum	31 \pm 23, 64 \pm 21
	3, 5, 6, 7, 8, 9		Dry	Drained_dry	-19.2 \pm 6.1	Carex	82 \pm 30
Control	0		Wet	Control_wet	-1.3 \pm 2.3	CarexShrub	85, 15
	1, 3, 6, 7, 8, 9		Wet	Control_wet	4.3 \pm 2.4	Eriophorum	79 \pm 33
	2		Wet	Conrol_wet	3.9 \pm 2.1	EriophorumShrub	80, 20
	4, 5		Dry	Control_dry	-18.5 \pm 4.1	CarexShrub	71 \pm 12, 27 \pm 15

Table 3 Two-way ANCOVA results with water table depth (WTD) category (high and low), and soil depth (cm) as the independent variables and soil temperature (°C) as the dependent variable. The time periods of the entire year of 2013, as well as three sub-seasons of 2014—(2014.1) 15 June–5 July, (2014.2) 6 July–26 July and (2014.3) 27 July–20 August—were separately analyzed. The significance of *F* values are denoted with asterisks (830 (*P* value < 0.001 ***, < 0.01 **, < 0.05 *).

	Transect	WTD	Depth	WTD × Depth
2013	Drained	12.75 ***	602.64 ***	13.38 ***
	Control	15.38 ***	700.93 ***	2.64
2014.1	Drained	3.54	169.46 ***	0.02
	Control	32.55 ***	165.35 ***	29.56 ***
2014.2	Drained	26.21 ***	400.48 ***	0.52
	Control	1.24	380.91 ***	2.42
2014.3	Drained	101.87 ***	680.50 ***	7.55 **
	Control	6.49 *	813.62 ***	4.91 *

835 Table 4 Average daily flux ($\text{g C-CO}_2 \text{ m}^{-2} \text{ day}^{-1}$) from interpolation for the period of 22 July to 10 August (20 days) in both 2013 and 2014. Values in parentheses are cumulative flux ($\text{g C-CO}_2 \text{ m}^{-2}$) for the period of 22 July to 10 August (20 days) in 2013 and 16 June to 20 August (66 days) in 2014. Results from 2013 represent the fits of all data points \pm standard deviation from bootstrapping, and those of 2014 represent mean \pm standard deviation from bootstrapping. Net ecosystem exchange (NEE) was calculated by subtracting gross primary production (GPP) from ecosystem respiration (R_{eco}): positive values are CO_2 emission to the atmosphere, and negative values are CO_2 uptake by the terrestrial ecosystem.

Year	Group	R_{eco}	GPP	NEE
2013	D_Carex	2.03 ± 0.10 (41 \pm 2)	3.42 ± 0.00 (68 \pm 0)	-1.38 ± 0.09 (-28 \pm 2)
	D_CarexEriophorum	1.89 ± 0.16 (38 \pm 3)	3.30 (66) ¹	-1.41 ± 0.24 (-28 \pm 5) ¹
	D_EriophorumShrub	1.88 ± 0.53 (38 \pm 11)	4.81 (96) ¹	-2.93 ± 0.34 (-59 \pm 7) ¹
	C_CarexShrub	2.04 ± 0.08 (41 \pm 2)	2.55 ± 0.02 (51 \pm 0)	-0.51 ± 0.05 (-10 \pm 1)
	C_Eriophorum	1.76 ± 0.05 (35 \pm 1)	3.41 ± 0.01 (68 \pm 0)	-1.65 ± 0.04 (-33 \pm 1)
	C_EriophorumShrub	2.34 ± 0.17 (47 \pm 3)	3.32 ± 0.00 (66 \pm 0)	-0.98 ± 0.14 (-20 \pm 3)
2014	D_wet (EriophorumShrub)	3.27 ± 0.16 (184 \pm 9)	7.59 ± 0.11 (404 \pm 6)	-4.31 ± 0.05 (-221 \pm 3)
	D_dry (CarexEriophorum)	3.51 ± 0.19 (200 \pm 9)	5.14 ± 0.07 (274 \pm 4)	-1.64 ± 0.11 (-74 \pm 5)
	C_wet (EriophorumShrub)	2.81 ± 0.24 (162 \pm 14)	5.85 ± 0.03 (312 \pm 1)	-3.05 ± 0.21 (-150 \pm 13)
	C_dry (CarexShrub)	3.98 ± 0.21 (222 \pm 12)	6.20 ± 0.03 (331 \pm 2)	-2.22 ± 0.18 (-109 \pm 10)

¹ As no bootstrapping was conducted on data for GPP, error range in NEE is only from ER.

Figure 1 A schematic showing how a decade-long drainage installation affects a floodplain ecosystem and CO_2 fluxes. Drainage of a floodplain ecosystem alters soil temperatures through changing heat capacity and thermal conductivity, with increased soil temperatures in shallow layers, decreased soil temperatures in deeper layers, and shallower thaw depths; and decreasing the abundance of wetland grasses while increasing the abundance of shrubs. These modifications will subsequently affect CO_2 fluxes by changing the rates of gross primary production and possibly increasing ecosystem respiration, which consists of autotrophic and heterotrophic respiration (R_a and R_h).

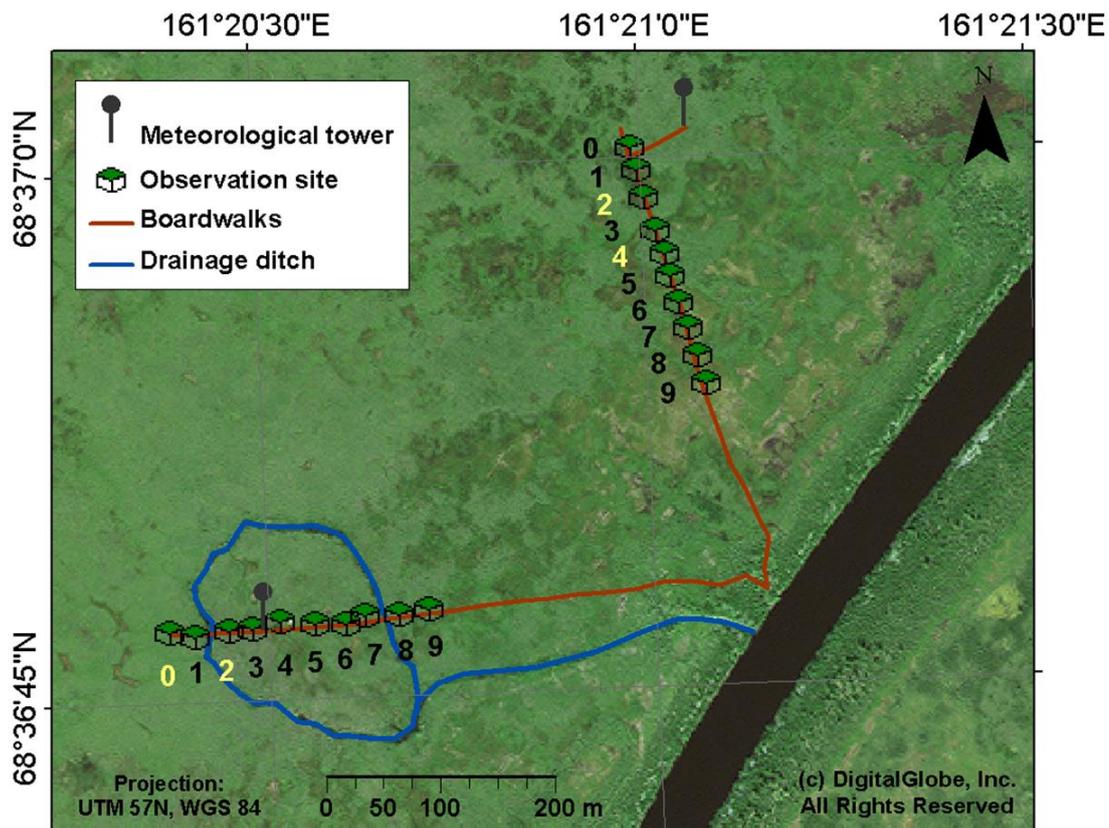

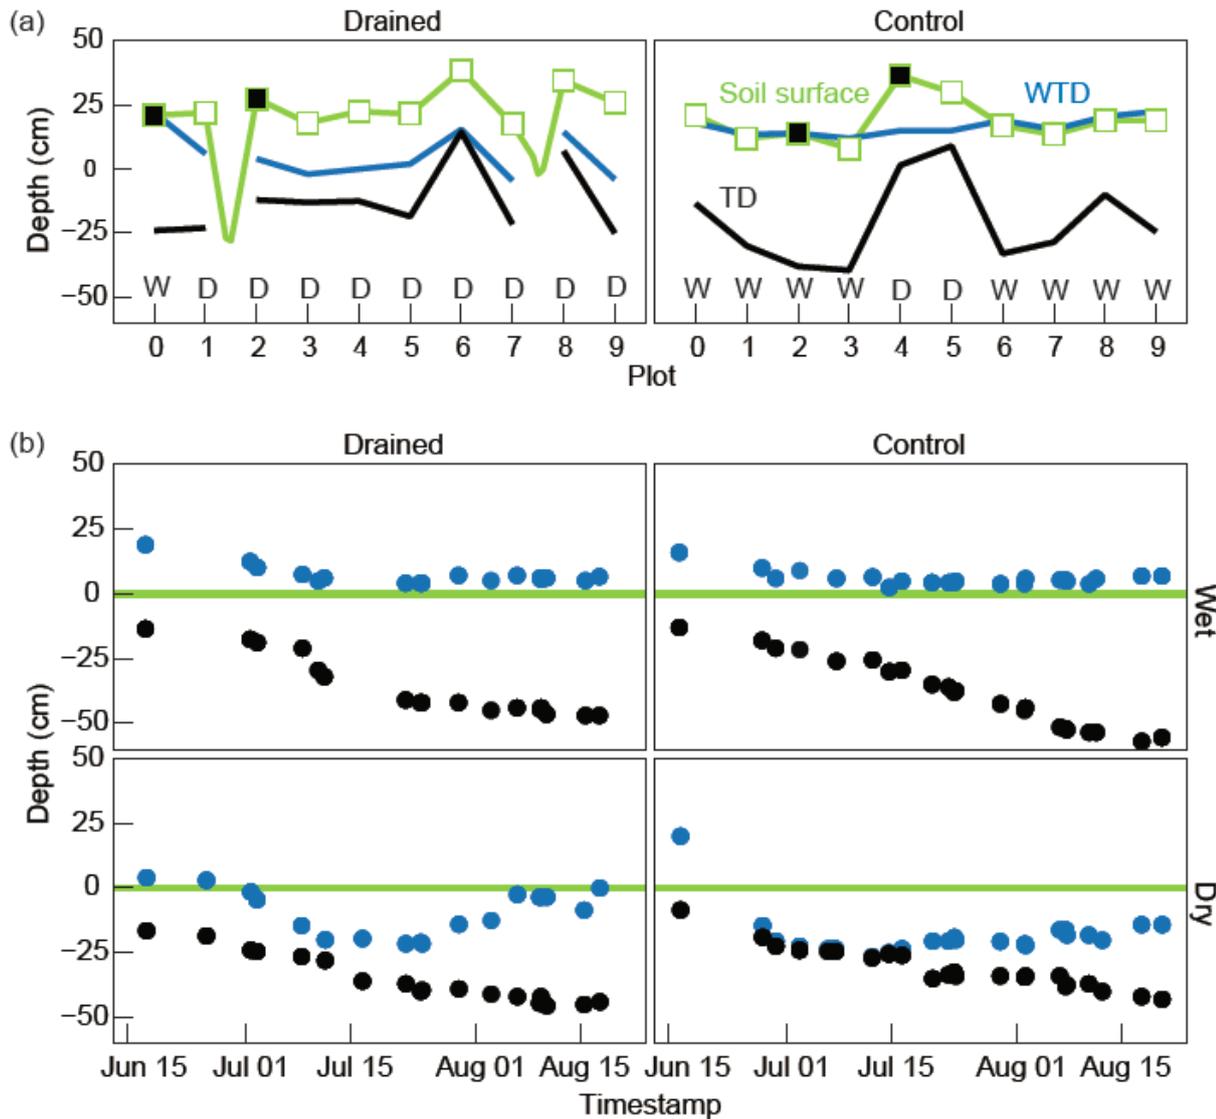

Figure 2 Aerial photograph of the site, including schematics of the drained (bottom left) and the control (top right) transects. Names of plots are written with numbers and two core plots for more frequent flux measurements are highlighted in yellow in each transect. Fluxes, vegetation community structures (created using a non-destructive method), water table depths, and thaw depths were measured in all plots, and soil temperatures were measured in even-numbered plots only.

855 Figure 3 (a) Spatial variability in water table depths (WTD, blue lines) and thaw depths (TD, black lines) measured across the two transects on 10 August, 2013. Green lines indicate terrain height, with plots indicated with squares (core plots = closed squares). The letters W and D indicate the wet and dry WTD category of each plot, respectively. (b) Temporal variability in WTD (blue points) and TD (black points) observed at the four core

plots over the growing season of 2014, separated by transect (columns) and WTD category (rows). Green lines

860 represent soil surface.

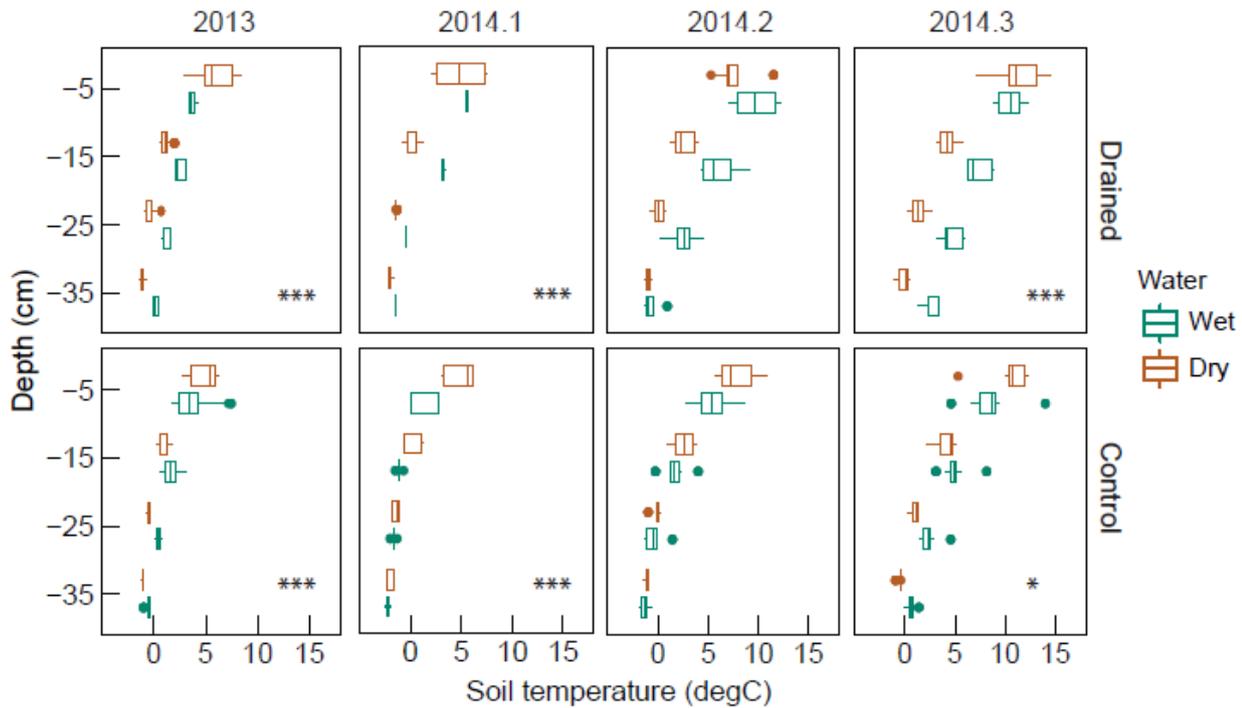

Figure 4 Soil temperature profiles based on observations at 5, 15, 25, and 35 cm depths from even-numbered plots each in the drained (top) and control (bottom) transects. Boxplot contains median, 25 % and 75 % quartiles, and ± 1.5 interquartile ranges. To minimize the impact of the diurnal temperature cycle on this temporally discontinuous dataset, the time window for averaging was restricted to 1 to 5 pm. Panels from left to right show data from 2013, as well as from three sub-seasons of the growing season of 2014: (2014.1) 15 June–5 July, (2014.2) 6 July–26 July and (2014.3) 27 July–20 August. Green color indicates wet plots and brown indicates dry plots. Data subsets where significant differences in WTD between the wet and the dry plots were detected are marked with asterisks (P value < 0.001 ***, < 0.01 **, < 0.05 *).

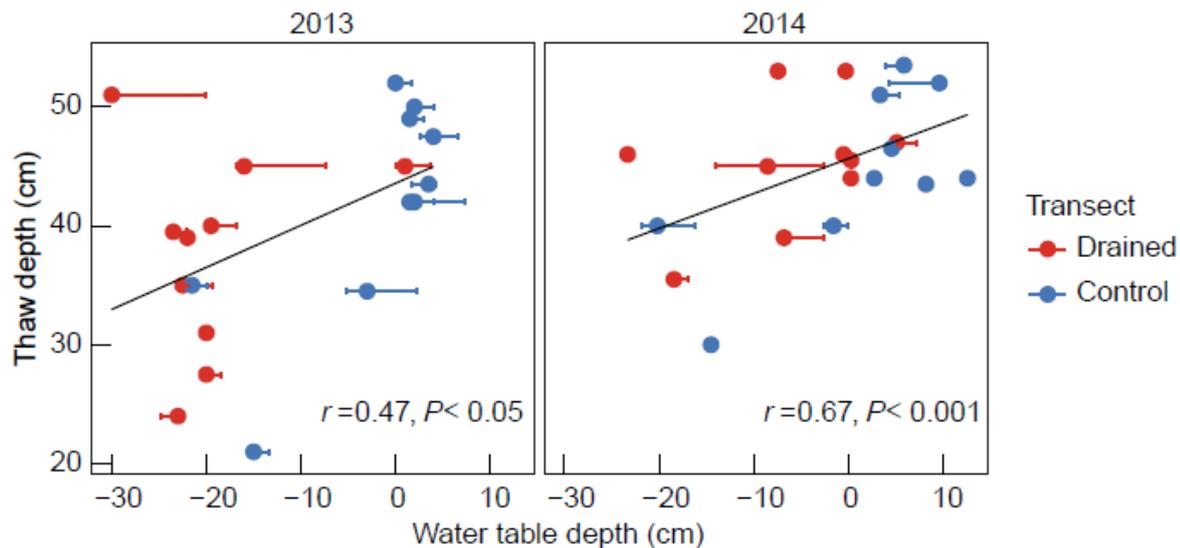

Figure 5 Correlations of thaw depths (TD) and water table depths (WTD) in mid-August 2013 and 2014, where red points indicate plots from the drained transect and, blue points plots from the control transect. Error bars of WTD represent the minimum and the maximum ranges of WTD of the previous 20 days. Results of correlation analysis for each year are presented with black lines.

875

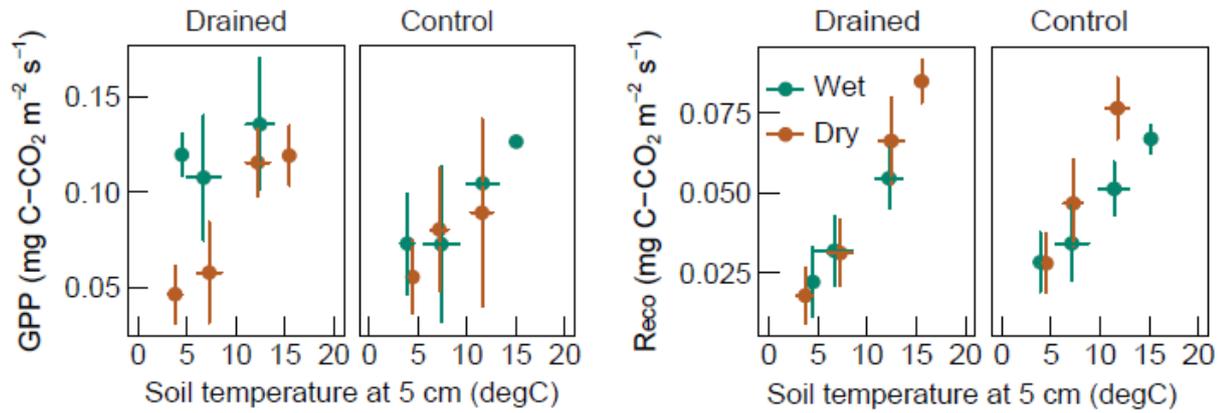

Figure 6 Links between average soil temperatures at 5 cm and gross primary production (GPP) and ecosystem respiration (R_{eco}) rates. Green color indicates wet plots and brown indicates dry plots. Data are from 2013 (20 July–10 August) and sub-season 2014.3 (27 July–20 August); both cover similar phenological periods. Data were grouped into temperature bins of 5 °C.

880

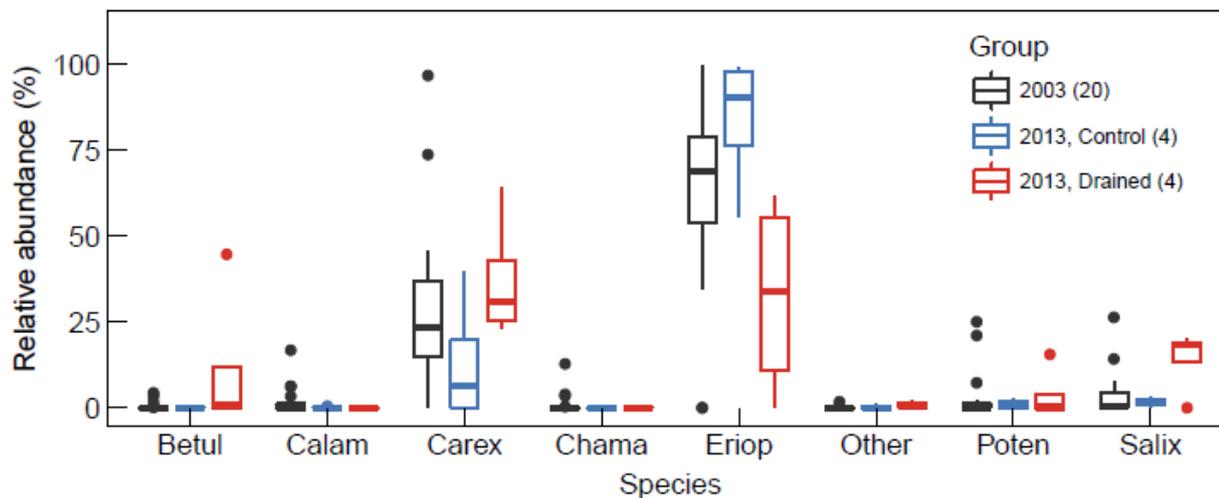

Figure 7 Abundances of vegetation species observed across the transects in 2003 and 2013. Numbers in parentheses are the number of replicates. Boxplot contains median, 25 % and 75 % quartiles, and ± 1.5 interquartile ranges. Betul: *Betula exilis*, Calam: *Calamagrostis purpurascens*, Carex: *Carex* species, Chama: *Chamaedaphne calyculata*, Eriop: *Eriophorum angustifolium*, Poten: *Potentilla palustris*, Salix: *Salix* species.

885

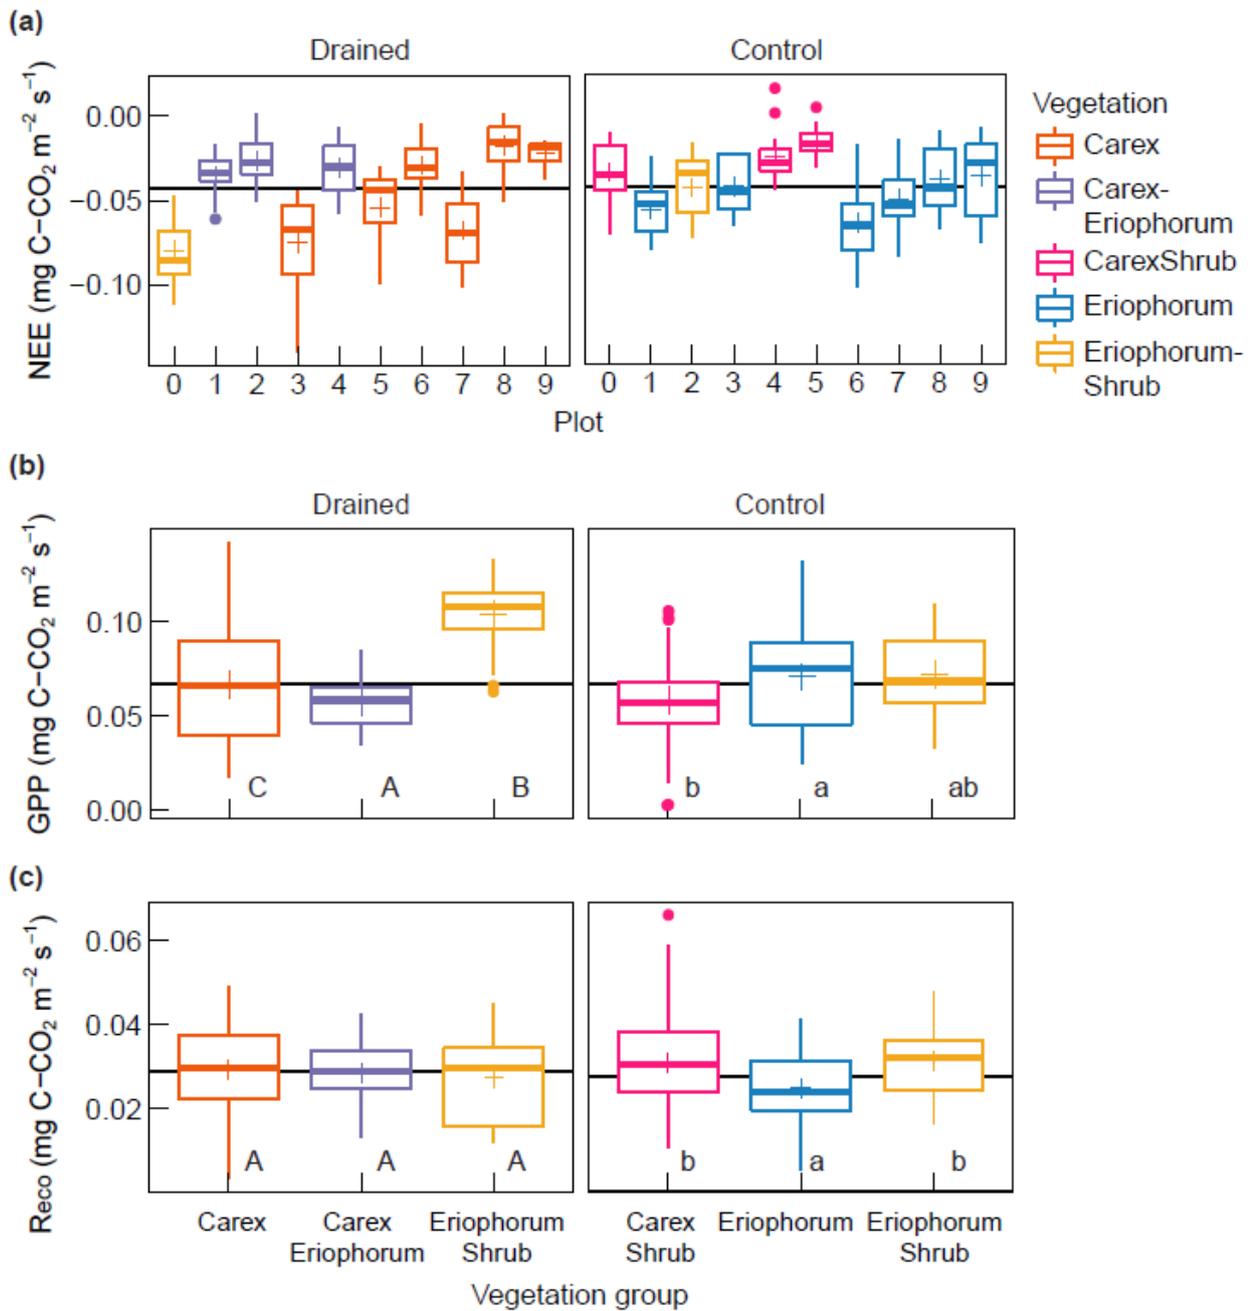

Figure 8 (a) Variability of net ecosystem exchange (NEE) among individual plots during the 2013 growing season. Boxplot contains median, 25 % and 75 % quartiles, ± 1.5 interquartile ranges, as well as mean values

890 with cross points per plot, with colors indicating the dominant vegetation species. The black horizontal bars show
the mean flux rates averaged for the entire transect. (b) Gross primary production (GPP) and (c) ecosystem
respiration (R_{eco}) rates aggregated by vegetation group. Significance of differences between groups, determined
by one-way ANOVA and Tukey's post hoc test, is indicated by the letters. Different letters indicate significant
differences between groups while the same letters indicate significant similarities.

895

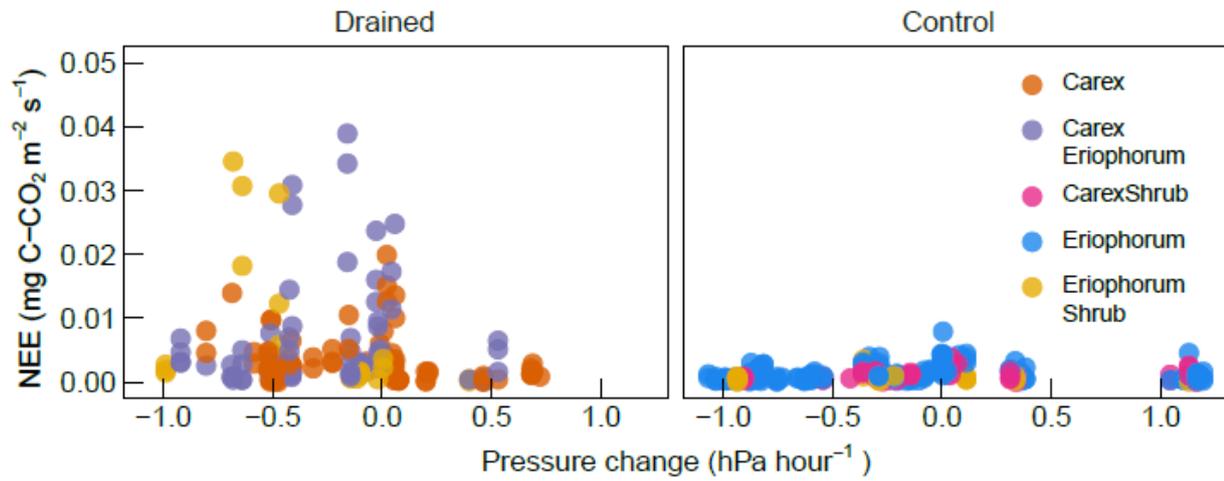

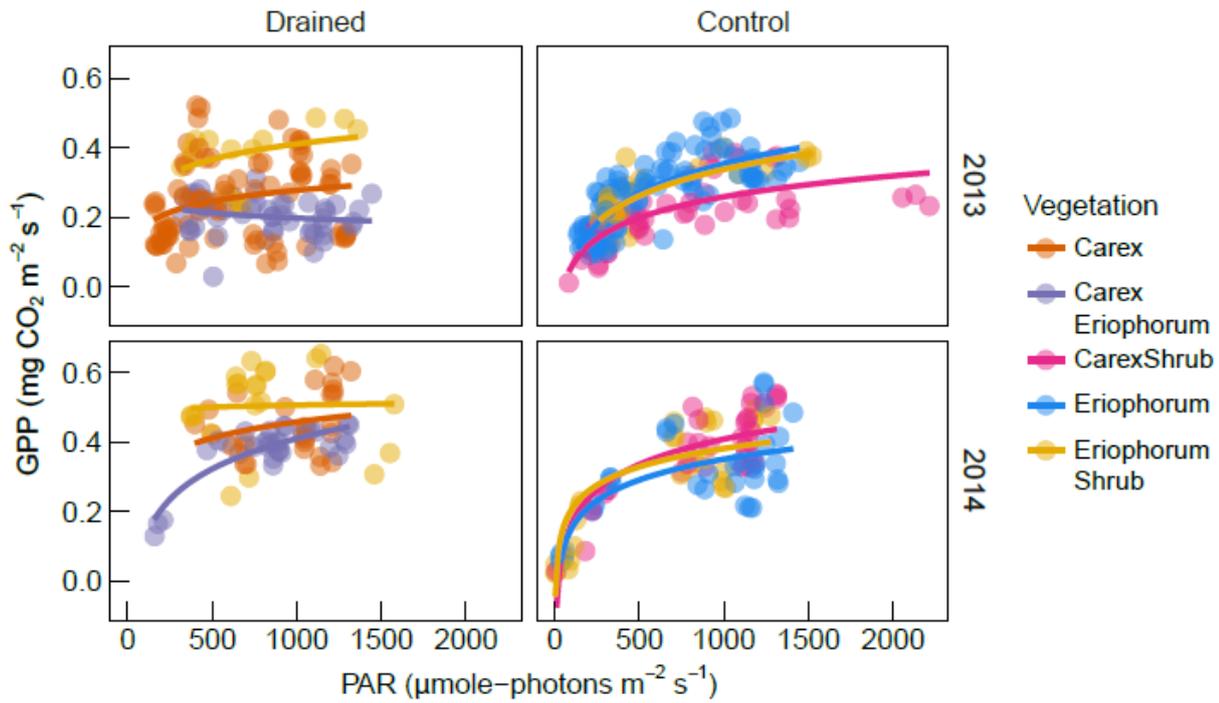

Figure 9 Change in atmospheric pressure and net ecosystem exchange (NEE) from November 2013 by vegetation type (color). Changes in atmospheric pressure refer to changes within 6 hours before individual NEE was measured.

900

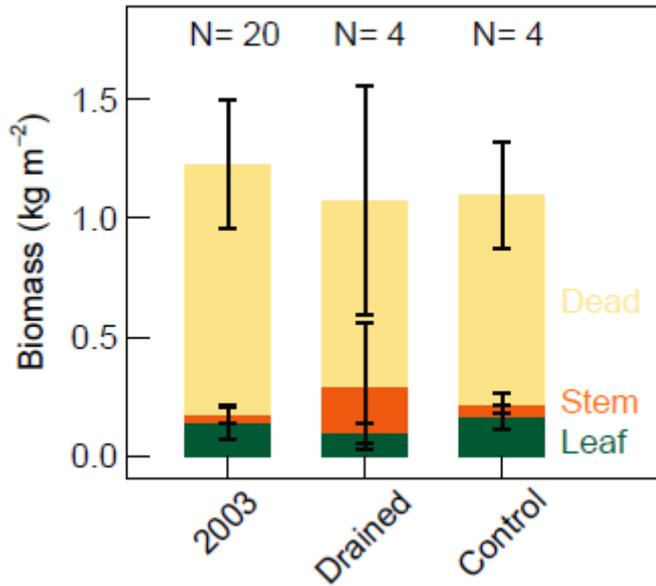

Supplementary Table 1 Root mean squared error (RMSE) and mean bias error (MBE) of the observed and interpolated fluxes ($\text{mg C-CO}_2 \text{ m}^{-2} \text{ s}^{-1}$). The observed fluxes indicate those used for calibration. Period of interpolation: 22 July to 10 August (20 days); values in parentheses for 2014: 16 June to 20 August (66 days).

Year	Group	Ecosystem respiration		Gross primary production	
		RMSE	MBE	RMSE	MBE
2013	D_Carex	0.009	0.00004	0.025	-0.035
	D_CarexEriophorum	0.007	-0.002	0.013	-0.001
	D_Eriophorumshrub	0.01	0.00005	0.026	-0.029
	C_CarexShrub	0.008	0.00002	0.016	-0.035
	C_Eriophorum	0.006	-0.00001	0.017	-0.027
	C_EriophorumShrub	0.007	0.000002	0.014	-0.034
	2014	D_wet (EriophorumShrub)	0.003 (0.007)	-0.0002 (-0.00004)	0.032 (0.03)
D_dry (CarexEriophorum)		0.008 (0.009)	0.003 (-0.00006)	0.02 (0.022)	0.003 (-0.054)
C_wet (EriophorumShrub)		0.01 (0.01)	-0.004 (-0.00002)	0.013 (0.023)	0.003 (-0.044)
C_dry (CarexShrub)		0.012 (0.011)	0.001 (0.0002)	0.023 (0.03)	0.002 (-0.091)

905

Supplementary Figure S1 Logarithmic relations between photosynthetically active radiation (PAR, X axis) and gross primary production (GPP, Y axis) by transect (columns), vegetation type (color) and year (rows). Data points are only from August when vegetation activity was high enough to minimize seasonality.

910

Supplementary Figure S2 The total aboveground dry biomass (mean ± standard deviation) of standing dead and living plants, measured in 2003 ($N = 20$) and 2013 ($N = 4$). Weights of dry biomass were not separated by species. Dead: standing dead materials, largely from *Carex* species and *Eriophorum angustifolium*; stem: stems, mainly from shrub species; leaf: green leaves of all species.
