21 sediment

22

23 **Running title:** Archive of microbial inhabitants in anhydrites

24

25 **Abstract**

26 In deep-sea sediment, the microbes present in anhydrite crystals after mild hydrothermal  
27 activities are markers of the past environment. In this study, this hypothesis was tested by  
28 analyzing the metagenome of an anhydrite crystal sample from a hydrothermal and  
29 hypersaline sediment core sampled from the Atlantis II Deep in the Red Sea. The 16S/18S  
30 rRNA genes in the metagenome were assigned to Bacteria, Archaea, Fungi and even  
31 invertebrate species. The dominant species in the crystals was an alkane-degrading  
32 *Alcanivorax* bacterium, which was not detected in the adjacent sediment layer. Using a  
33 genome-binning method, a draft genome of the *Alcanivorax* bacterium was separated from  
34 the metagenome. Phylogenetic and genomic analyses revealed that this species was a close  
35 relative of *Alcanivorax borkumensis* Sk2. The draft genome contained all the functional  
36 genes for alkane utilization and the reduction of nitrogen oxides. Fluorescence microscopy  
37 using 16S rRNA and marker gene probes revealed intact cells of the *Alcanivorax* bacterium  
38 in the crystals. Moreover, the metagenomes of the anhydrites and control sediment  
39 contained aromatic degradation pathways, which were mostly derived from *Ochrobactrum*  
40 sp. The estimated age of the anhydrite layer was between 750-770 years, which might span  
41 the event of hydrothermal eruption into the benthic floor. Altogether, these results support  
42 the presence of an oxic, oil-spilling benthic environment in the Atlantis II basin of the Red  
43 Sea in approximately the 14th century. The original microbial inhabitants underwent a  
44 dramatic selection process via drastic environmental changes following the formation of  
45 an overlying anoxic brine pool in the basin due to hydrothermal activities.

46

47

48

## 49 1. Introduction

50 Deep-sea sediment is among the least explored biospheres on Earth. Indigenous microbes  
51 differ vastly in community composition and metabolic spectra at different depths and sites  
52 <sup>1,2</sup>. The distribution of microbes in subsuperficial sediments is determined by the porosity,  
53 nutrient availability and geochemical conditions of the sediment <sup>3,4</sup>. Variations in these  
54 parameters in sediment layers lead to the stratification of microbial communities. In return,  
55 genomic features and the community composition of the indigenous microbial inhabitants  
56 may reflect the *in situ* conditions. However, dead microbes cannot be well preserved and  
57 will be degraded by biological and abiological activities. Most of the biological markers  
58 containing the geochemical indicators were lost due to lack of preservation processes.  
59 Although lipids and other organic carbons present in some minerals allow the prediction  
60 of microbial activities to some extent <sup>5</sup>, the original metabolic activities have been difficult  
61 to retrieve in a comprehensive and precise manner.

62

63 Although most of the dead microbes are damaged during the sedimentation process, some  
64 likely can be maintained in almost their original shape. Evaporites, which mostly consist  
65 of halite and anhydrite (CaSO<sub>4</sub>) or gypsum (CaSO<sub>4</sub>·2H<sub>2</sub>O, temperature <38°C <sup>6</sup>), are  
66 common microbialites with accretionary organosedimentary structures <sup>7</sup>. Numerous dead  
67 bacteria, algae and metazoans have been detected in gypsum granules <sup>8,9</sup>; bacterial mats  
68 growing on evaporites may become trapped and constitute much larger microbialites <sup>10</sup>.  
69 Consequently, microbial inhabitants on the benthic surface become trapped in the  
70 evaporites. Anhydrite facies are not found throughout deep-sea sediments. They usually  
71 form around hydrothermal vents in deep-sea environments <sup>11</sup>. A strong deep-sea volcanic  
72 eruption may break the crustal basalts, resulting in a drastic emission of hydrothermal gases  
73 followed by the crystallization of anhydrites and the deposition of metal sulfides <sup>12</sup>. An  
74 alternative model is that mild hydrothermal activities lead to a slow influx of solutions into  
75 the overlying sediment at temperatures in the sub-seafloor ranging from 20-100°C. This  
76 process also results in the formation of crystalline anhydrites in veins and around warm  
77 vents <sup>11</sup>. The latter process may trap microbial inhabitants on the seafloor and within  
78 surface layers in anhydrites. Due to the mild temperature, the trapped bodies are better  
79 preserved as excellent biological markers that contain hints of past geochemical conditions.

80

81 A similar geological setting is present in the Red Sea. Initially located in a deep-sea rift in  
82 the 1960s<sup>13,14</sup>, the temperature of the Atlantis II brine pool has recently increased to 68°C  
83<sup>15</sup>. In 1972, several sediment cores were obtained from the southwest region of the pool  
84 (DSDP Site226), and metal sulfides and evaporites were recognized as major mineral facies  
85 in this brine-filled basin<sup>16</sup>. In particular, thick and well-crystalized anhydrite layers were  
86 found within the hematite and at the bottom of the cores. Two major anhydrite units were  
87 later defined by analysis of the adjacent core samples. The lower unit comprised anhydrite  
88 ranging from 12 to 70 wt%<sup>17</sup>. The anhydrite in the sediments likely resulted from a geyser-  
89 type eruption of hydrothermal solutions into the Atlantis II brine pool followed by the  
90 mixing of calcium-rich solutions with dissolved sulfate-bearing brine and the precipitation  
91 of anhydrites during the cooling process<sup>18</sup>. The discovery of veins containing sulfides and  
92 anhydrite in the sediment suggests that a mild hydrothermal eruption created the anhydrite  
93 facies in the Atlantis II sediment<sup>19-21</sup>. The formation of anhydrite facies in this manner  
94 would trap microbial cells and organic debris in the bottom water and surface sediment.  
95 Hence, these anhydrite layers probably contained important indigenous microbial  
96 inhabitants during the occurrence of the hydrothermal events at the deep-sea benthic floor  
97 of the Red Sea. Coupled with other markers to estimate age, the anhydrite facies probably  
98 contained a large quantity of information regarding the past geochemical changes.

99

100 In the present study, we sampled a sediment core near Site226 and detected an anhydrite  
101 layer. Microbial DNA was extracted from the crystals and sequenced for the metagenomic  
102 study. The dominant species were alkane- and oil-degrading bacteria, together with some  
103 archaeal species. In contrast, the microbial community residing in the neighboring control  
104 sediment differed substantially from that in the anhydrite crystals. The present study sheds  
105 light on the importance of anhydrites in deep-sea sediment as an archive of microbial  
106 inhabitants that can serve as biomarkers of past geochemical events.

107

## 108 **2 Materials and methods**

### 109 **2.1 Physicochemical measurements of sediment layers**

110 In 2008, a 2.25-meter gravity sediment core was obtained from the southwest basin  
111 (approximately 2180 meters below sea level) of the Atlantis II Deep (21°20.76' N,  
112 38°04.68' E) in the Red Sea <sup>22</sup>. The core was frozen at -80°C and then sliced aseptically  
113 into seventy-five 3-cm sections. Microbes from sediment slices of 12-15 cm, 63-66 cm,  
114 105-108 cm, 183-186 cm, and 222-225 cm were first suspended in phosphate-buffered  
115 saline and shaken on a vortexer for 30 s. The supernatant was filtered through a 0.22- $\mu$ m  
116 black polycarbonate filter. After 6-diamidino-2-phenylindole (DAPI) staining, the  
117 microbes from each layer were counted under an epifluorescence microscope (n = 3) <sup>23</sup>.  
118 The pore water from the above 5 layers was collected by centrifugation. The concentration  
119 of dissolved organic carbon (DOC) in the pore water was determined using the combustion  
120 method <sup>9</sup>. The concentrations of ammonium, nitrite and nitrate were measured using a  
121 TNM-I analyzer (Simadzu, Kyoto, Japan). To separate large particles (>63  $\mu$ m) from small  
122 particles (<63  $\mu$ m), the sediment samples were passed through a 63- $\mu$ m stainless steel sieve.  
123 The percentage of small particles (dry weight) was calculated for all slices.

124

125 The age of the sections was estimated with a radiometric dating method that utilizes the  
126 naturally occurring radioisotope <sup>14</sup>C. The monospecific *Globigerinoides sacculifer*  
127 specimens ranging in size from 250 to 350  $\mu$ m were manually selected with caution and  
128 then subjected to <sup>14</sup>C measurement in the National Ocean Sciences Accelerator Mass  
129 Spectrometry (AMS) Facility at the Woods Hole Oceanographic Institute, USA. The raw  
130 AMS <sup>14</sup>C ages were converted to calendar ages using the CALIB 6.0 program  
131 (<http://calib.qub.ac.uk/calib/>) with the dataset Marine 09 <sup>24</sup>. A reservoir correction has been  
132 considered for the <sup>14</sup>C difference between atmospheric and surface waters <sup>25</sup>.

133

## 134 **2.2 DNA extraction and amplification**

135 The boundary of the anhydrite layer was determined by naked eye observation and particle  
136 size measurement. Crystals were manually collected from the layers, followed by  
137 ultrasonic cleaning. The grounded crystals were then analyzed by X-ray diffraction (XRD)  
138 (Rigaku, Tokyo, Japan) using Cu Ka radiation of 40 kV and 30 mA. The following  
139 procedure was conducted for DNA extraction from the crystals with caution to avoid  
140 contamination. Surface contamination was removed by rinsing with 70% alcohol in

141 autoclaved distilled deionized water, followed by pulsed ultrasonic cleaning for 2 hours.  
142 Anhydrite crystals (20 g) (Fig. 1A) of different sizes were treated with 1  $\mu$ L (2U) Turbo  
143 DNase I (Ambion, Austin, Texas, US) for 30 m in a 37°C incubation before being ground  
144 for DNA extraction in a sterile hood. The anhydrite powder was used for DNA extraction  
145 with the PowerSoil DNA Isolation kit (MO-BIO, Carlsbad, USA), followed by a  
146 purification step according to the manufacturer's instructions. Twenty picograms of the  
147 raw DNA extract was used for DNA amplification using a MALBAC kit (Yikang, Jiangsu,  
148 China) according to the manufacturer's manual <sup>26</sup>. The MALBAC amplification method  
149 has been evaluated recently in metagenomic studies <sup>27</sup>. Two MALBAC amplification  
150 assays were conducted using twenty-one PCR cycles to acquire a sufficient amount of  
151 DNA for subsequent sequencing. A negative control was also incorporated in the assay.  
152 The DNA concentration of the MALBAC-amplified sample and the negative control was  
153 measured with a Bioanalyzer (Agilent, CA, US). The products of the MALBAC  
154 amplification and negative control were examined by gel electrophoresis to validate the  
155 size ranges of the amplicons. Three replicates of MALBAC amplifications for each sample  
156 were mixed and used for Illumina sequencing on a Hiseq2500 platform. As a control, 10 g  
157 of sediment from a position at 168 cm from the top of the core was used for DNA extraction.  
158 There were no recognizable anhydrite crystals in this layer. DNA amplification and  
159 sequencing were conducted as described above.

160

## 161 **2.2 Binning of metagenomes**

162 The initial Illumina 2 $\times$ 110-bp paired-end reads were subjected to quality assessments using  
163 the NGS QC Toolkit with default parameters (Patel and Jain, 2012). The Illumina  
164 sequencing data were deposited in the NCBI SRA database (accession number  
165 SRA356974). The 35-bp MALBAC adapters at the start of the sequencing reads were  
166 removed. Assembly of the trimmed Illumina 2 $\times$ 75-bp paired-end reads was performed  
167 using SPAdes 3.5 <sup>28</sup>. The read coverage for the assembled contigs was calculated using  
168 SAMtools <sup>29</sup>. The 16S/18S rRNA genes in the contigs were identified using rRNA\_HMM  
169 <sup>30</sup>. Taxonomic sorting of the 16S rRNA genes was conducted in the SILVA database with  
170 a confidence threshold of 80%. The relative abundance of the species in the metagenomes  
171 was roughly estimated based on the coverage of the 16S/18S rRNA genes. Binning of the

172 draft genomes was performed based on the read coverage and G+C content of the contigs  
173 (Fig. 1B), followed by principal component analysis (PCA) of the tetranucleotide  
174 frequencies (TNF) of their respective contigs using a previously described pipeline (Fig.  
175 1C) <sup>31</sup>. The binning process was visualized with the RStudio program  
176 (<https://www.rstudio.com>). To evaluate the completeness of the draft genome, conserved  
177 single-copy genes (CSCGs) were counted in the genome. The CSCGs were identified by  
178 searching the CDSs against an HMM database of essential bacterial genes (107 essential  
179 genes) <sup>31</sup> using *hmmsearch* (3.0) with default cutoffs for each protein family.

180

### 181 **2.3 Genomic analyses**

182 The coding DNA sequences (CDSs) of the draft genome were predicted using Prodigal  
183 (version 2.60) <sup>32</sup>. KEGG annotation of the CDSs was performed using BLASTp against the  
184 KEGG database <sup>33</sup> with a maximum e-value cutoff of 1e-05. The KEGG pathways were  
185 reconstructed using the KEGG website (<http://www.kegg.jp>). CDSs were also annotated  
186 against the NCBI NR database, and MEGAN was used for taxonomic affiliation and  
187 SEED/subsystem annotation of the CDSs <sup>34</sup>. The draft genome was submitted to NCBI  
188 (accession number LKAP00000000). The average nucleotide identity (ANI) was  
189 calculated using the algorithm integrated in the web service of EZGenome <sup>35</sup>. The DNA-  
190 DNA hybridization (DDH) estimate value was calculated using the genome-to-genome  
191 distance calculator (GGDC2.0) with the alignment method of BLAST+ <sup>36-38</sup>.

192

### 193 **2.4 Detection and phylogeny of 16S ribosomal RNA (rRNA) genes**

194 The 16S rRNA gene sequence was identified from the draft genome sequence. The  
195 closest relatives based on 16S sequence similarity were determined using the web service  
196 of EzTaxon <sup>39</sup>. The neighbour-joining phylogenetic tree was constructed using MEGA  
197 version 5.0 <sup>40</sup> with the Kimura 2-parameter model. The phylogenetic tree was supported  
198 with bootstrap values based on 1000 replications.

199

### 200 **2.5 Fluorescence *in situ* hybridization (FISH) of *Alcanivorax* bacteria**

201 FISH probes for *Alcanivorax* bacteria were designed using the 16S rRNA gene extracted  
202 from the *Alcanivorax* draft genome. Two 16S rRNA fragments, 5'-

203 CCTCTAATGGGCAGATTC-3' and 5'-CCCCCTCTAATGGGCAGA-3', were selected  
204 as candidate probes with Probe\_Design in the ARB package<sup>41</sup>. The coverage efficiency of  
205 the probes was then examined in the Silva database<sup>42</sup>. The 6-FAM-labeled probe used to  
206 target the *alkB* gene was 5'-ATGGAGCCTAGATAATGAAGT-3'<sup>43</sup>. A pure culture of  
207 *Alcanivorax borkumensis* Sk2 was first used to examine the probes before performing the  
208 assay. Two grams of anhydrite crystals were sonicated for 30 min in 1 U DNase I solution.  
209 The crystals were washed with deionized water and then ground into a powder with a  
210 beadbeater in a germ-free environment. The supernatant was mixed with 37%  
211 formaldehyde (final concentration, 1-4%). To fix the cells in PBS buffer, the sample was  
212 maintained at 4°C for 3-4 hr. After centrifugation at 13,000 r/min for 3 min, the supernatant  
213 was discarded. The remaining microbes were soaked in 200 µL of PBS buffer, followed by  
214 addition of 200 µL of ethanol<sup>44</sup>. The sample was filtered through 3-µm and 0.22-µm  
215 membranes sequentially (diameter, 25 mm; Millipore, Eschborn, Germany). After  
216 dehydration of the membrane using alcohol, 2 µL of dye solution containing  
217 oligonucleotide probes and 20 µL of buffer (360 µL of 5 M NaCl, 40 µL of 1 M Tris/HCl,  
218 700 µL of 100% formamide, 2 µL of 10% SDS, and water to a total volume of 2 mL).  
219 The hybridization of the probes to the microbes was performed for 2 h at 46°C. Rinsing  
220 buffer (700 µL of 5 M NaCl, 1 mL of 1 M Tris/ HCl, 500 µL of 0.5 M EDTA, 50 µL of  
221 10% SDS and water to a total volume of 50 mL) was used to remove free probes. For  
222 counterstaining, 50 µL of 4', DAPI solution (1 µg/mL) was added to the sample. After  
223 incubation for 3 min, the sample was washed in MQ (MetaPhor Bioproducts, Rockland,  
224 Maine) and 96% ethanol for 1 min<sup>44</sup>. The microscopic observation was conducted using  
225 an Olympus BX51 (Olympus, Tokyo, Japan).

226

## 227 **3 Results**

### 228 **3.1 Physicochemical profile and cell counts**

229 A thick anhydrite layer was present at the bottom of the sediment core based on naked-eye  
230 observation of the color and grain size. The anhydrite layer at depths ranging from 177-  
231 198 cm consisted of coarse, agglutinated crystals, which corresponded to the high  
232 percentage of large grains (78 wt% larger than 63 µm) (Fig. 2). The XRD analysis further  
233 confirmed that the crystals in this layer were anhydrite. In contrast, halite comprised the

234 evaporites at depths of 12 cm, 63 cm, 105 cm and 222 cm. For the samples at different  
235 depths, the DOC concentration was measured, and the highest value was recorded at 183  
236 cm ( $80.9 \text{ mg L}^{-1}$ ), which was even higher than the surface layer at 12 cm (Fig. 3). In the 12  
237 cm layer, the cell density was  $3.2 \times 10^5$  cells per  $\text{cm}^3$ , whereas in the layers at 63 cm, 105  
238 cm and 222 cm, it was reduced by 88%, 92% and 96%, respectively (Fig. 3). The cell  
239 density was also calculated as the number of cells per gram of sediment. The results  
240 revealed a value of  $7.1 \times 10^5$  cells per gram at a depth of 12 cm, which declined more than  
241 70% in the deeper layers. Although the cell density in the 183 cm layer ( $6.7 \times 10^4$  cells/ $\text{cm}^3$ )  
242 was markedly lower than that in the 12 cm layer, it was higher than those in the 105 cm  
243 and 222 cm layers.

244

245 The sediment as a whole is a highly reductive environment, as indicated by the low nitrate,  
246 low nitrite and extremely high ammonium concentrations (Fig. 3). To determine the time  
247 of the anhydrite layers at 177-198 cm, an age estimate was performed for several layers.  
248 The sediment ages were estimated based on the radioisotope  $^{14}\text{C}$  of *G. sacculifer* assuming  
249 a linear increment from the top (Fig. 2). The results obtained for the layers above and below  
250 the anhydrite layer indicated a narrow range of 750-770 years between 153 cm and 198 cm  
251 (Table 1).

252

### 253 **3.2 Draft genome of the dominant bacterial species in anhydrites**

254 DNA was extracted from the anhydrite crystals and the adjacent layer separately. After  
255 amplification, about 16 Gbp Illumina sequencing data were obtained and then assembled.  
256 The size of the anhydrite and control metagenomes was 59 and 84 Mbp, respectively, after  
257 assembly. The microbial communities differed remarkably according to the taxonomic  
258 assignment of the 16S/18S rRNA gene fragments in the two metagenomes (Fig. 4). At the  
259 genus level, only *Ochrobactrum* and *Alkanindiges* were common inhabitants in both  
260 samples. *Alcanivorax* and *Bacillus* were also dominant genera in the anhydrite and the  
261 control, respectively. At the phylum level, excluding the Proteobacteria, the two  
262 metagenomes had distinctive phyla. The anhydrite contained Archaea that were  
263 represented by the methanogenic *Methanoculleus*<sup>45</sup>; and Fungi that consisted of the  
264 Ascomycota. In contrast, the control sediment contained mainly Firmicutes, Bacteroides,

265 Actinobacteria, and Deinococcus-Thermus. Surprisingly, an invertebrate species,  
266 *Prototritia* sp. belonging to Arthropoda, was identified in the anhydrite.

267

### 268 **3.3 Genome binning of an *Alcanivorax borkumensis* genome**

269 The binned draft genome from the anhydrite metagenome was 3,069,971 bp and comprised  
270 77 contigs. A partial 16S rRNA gene sequence (805 bp) was extracted from the draft  
271 genome. Because the sequence was almost identical to that of *A. borkumensis* Sk2 (99.9%),  
272 we considered the binned draft genome to be from a strain of *A. borkumensis*. As shown in  
273 Figure 5, a phylogenetic tree based on the 16S rRNA gene sequences of the genus  
274 *Alcanivorax* indicated that the strain clustered with *A. borkumensis* Sk2, an exclusive and  
275 ubiquitous hydrocarbon-degrading bacterium<sup>46,47</sup>. The strain name of the *A. borkumensis*  
276 in the sediment core was ABS183. The coverage levels of the contigs ranged from 100-  
277 fold to 200-fold (Fig. 1B). Due to its highest level of coverage in the metagenome, *A.*  
278 *borkumensis* ABS183 was probably the most dominant species in the anhydrite crystals. It  
279 was the only microbial species that could be reliably separated from the metagenome.

280

281 The genome of *A. borkumensis* ABS183, despite containing gaps, was slightly smaller than  
282 that of *A. borkumensis* Sk2 (accession number NC\_008260; 3,120,143 bp), suggesting that  
283 the draft genome of *A. borkumensis* ABS183 was nearly complete. The identification of a  
284 complete list of single-copy genes also supported the completeness of the genome. The  
285 DDH estimation between *A. borkumensis* ABS183 and Sk2 was 97.1%±1.3%, which was  
286 higher than the standard cut-off value of 70% for genome relatedness between pairs of  
287 species<sup>48</sup>. The ANI value between ABS183 and Sk2 was 99.9%, which was also higher  
288 than the standard ANI criterion for species identity (95%–96%)<sup>49</sup>. These results further  
289 confirmed that ABS183 was a strain of *A. borkumensis*.

290

291 The genome of *A. borkumensis* ABS183 contains two copies of the alkane-1  
292 monooxygenase gene (*alkA*; 10502\_28 and 2890\_35), which is an essential functional gene  
293 for alkane utilization by *Alcanivorax* bacteria<sup>46</sup>. Neighboring the *alkA* genes, *alkBGHJ*  
294 genes, a GntR family transcriptional regulator gene, and a rubredoxin gene were identified.  
295 The gene order of the related genes was consistent with that of the homologs in the genome

296 of strain Sk2<sup>46</sup>. The *alk* genes were completely absent from the control metagenome.  
297 Moreover, the genome of *A. borkumensis* ABS183 contains genes responsible for the  
298 reduction of nitrogen oxides (KEGG genes: K00370-K00374 and K00362-K00363; nitrate  
299 reductase I genes and nitrite reductase genes). The reduction process was believed to  
300 generate ammonia for the efficient synthesis of amino acids<sup>46</sup>. A high demand for fatty  
301 acids was a characteristic of *A. borkumensis* to perform rapid energy and organic carbon  
302 storage. *A. borkumensis* ABS183 was probably able to synthesize long fatty acids because  
303 the *fas* and *fabBFGIKZ* genes responsible for the elongation of fatty acids were all present  
304 in its draft genome. In contrast, the essential *fas* gene (K11533) and other relevant genes  
305 were not found in the control metagenome. Crude oil generally contains aromatic  
306 compounds, and the current sediment at the sampling site also contained oil<sup>50</sup>. As expected,  
307 the two metagenomes possessed a complete set of genes responsible for the degradation of  
308 aromatic compounds. Based on the homology of the genes, the *Ochrobactrum* and  
309 *Alkanindiges* species probably played a role in this degradation.

310

#### 311 **3.4 Detection of bacteria in anhydrite crystals by DAPI and FISH**

312 To determine whether complete microbial cells could be maintained in the anhydrite  
313 crystals, DAPI and FISH assays were conducted to visualize the microbes. The DAPI  
314 results revealed the presence of complete cells that were released or embedded in the  
315 crystals (Fig. 6A, D, and H). However, the FISH assay, which was used to detect *A.*  
316 *borkumensis* ABS183 with two probes specific to the 16S rRNA gene, showed some  
317 fluorescence-labeled microbes (Fig. 6B, E and I). These microbes could also be envisioned  
318 with the FISH assay using the *alkB* gene probe (Fig. 6F and 6J). The *alkB* is one of the  
319 functional genes that participate in alkane degradation<sup>46</sup>. The rod shape of the fluorescent  
320 microbes is consistent with the microscopic features reported previously<sup>47</sup>. These results  
321 indicated that some microbes in the microscopic fields were *A. borkumensis* ABS183, as  
322 revealed in the anhydrite metagenome.

323

#### 324 **4 Discussion**

325 In the present study, we detected complete microbial cells and analyzed their metagenome  
326 in the anhydrite crystals from a deep-sea anoxic basin. The dominant bacterial species was

327 *A. borkumensis* ABS183, an aerobic bacterium that is capable of degrading alkanes in crude  
328 oil. *Alcanivorax* is one of the bacterial indicators for the spilling of oil in waters and surface  
329 sediment<sup>51</sup>. However, the Atlantis II brine pool is anaerobic and increasingly hydrothermal  
330<sup>52</sup>. The brine sediment in the basin was also found to be anoxic. Thus, *A. borkumensis*  
331 ABS183 could not be current inhabitants of the hydrothermal anoxic basin. This difference  
332 did not explain the stratification of microbial communities in the different sediment layers  
333 of the brine-filled basin. A recent study showed that *Alcanivorax* was not present in all  
334 sediment layers of a sediment core from the Atlantis II basin<sup>53</sup>. A reasonable explanation  
335 for this finding is that the anhydrite layer at 177-198 cm in the sediment core was formed  
336 at a previous benthic site when hydrothermal solution was injected into the seafloor. The  
337 organisms living in the benthic water and subsurface sediment were subsequently sealed  
338 and protected in the anhydrite crystals. Because the metabolism of *A. borkumensis* bacteria  
339 was specifically used for the degradation of alkanes and other hydrocarbons in crude oil<sup>51</sup>,  
340 the benthic site in which the anhydrite layer formed was probably an oil-spilling or oil-  
341 forming environment in the Atlantis II basin. The current hot sediments in the basin are  
342 biogenic and abiogenic sources of crude oil<sup>54</sup>. Seeping of the oil has resulted in  
343 proliferation of *A. borkumensis* bacteria in the bottom water. Similarly, oil-utilizing  
344 bacteria were nourished after the oil-spilling disaster in the Gulf of Mexico<sup>55</sup>.

345

346 Based on the results in the present study, we postulated that mild eruptions of hydrothermal  
347 solutions injected calcium-rich solutions into the seafloor and produced anhydrite veins by  
348 mixing with sulfate in the bottom water of the Atlantis II rift basin. The anhydrite layer  
349 was then covered by sulfide minerals and biological debris such as the planktonic  
350 foraminifera *G. sacculifer*. In this study, we narrowed the age of the thick anhydrite layer  
351 to 750-770 years using <sup>14</sup>C isotope of the *G. sacculifer* specimens. This result also indicates  
352 a relatively young sediment age and a high accumulation rate of precipitated metals in the  
353 Atlantis II basin. Because the upward movement of hydrothermal solutions might transfer  
354 some foraminifera specimens from lower layers to the anhydrite layer, we did not use the  
355 foraminifera between anhydrite crystals. In our previous study, we have shown evidence  
356 of oil formation in the Atlantis II brine pool<sup>50</sup>. The organic carbon content can be converted  
357 to aromatic compounds under the hydrothermal conditions in the pool based on chemical

358 and metagenomic evidence<sup>50</sup>. However, the bottom of the anoxic brine pool was not a  
359 habitat of *Alcanivorax* species<sup>56,57</sup>, suggesting that *Alcanivorax* flourished in the basin  
360 before the formation of brine water layers over the sediment<sup>57</sup>.

361

362 Although there were differences in microbial communities between the anhydrite crystals  
363 and the control sediment, *Ochrobactrum* sp. was one of the common inhabitants. Previous  
364 studies have shown that *Ochrobactrum* species could metabolize aromatic compounds  
365 aerobically and anaerobically<sup>58,59</sup>, which explains their presence in both metagenomes  
366 assessed in the current study. Moreover, we determined the concentrations of nitrogen  
367 oxides in the different sulfide layers, although only low concentrations were detected.  
368 *Ochrobactrum* species were potentially able to anaerobically degrade polycyclic aromatic  
369 compounds using nitrate as an oxygen donor<sup>59,60</sup>. Such a chemolithoheterotrophic lifestyle  
370 is in accordance with the current *in situ* environment of the sediment in the Atlantis II.  
371 Regardless of the environmental changes indicated by the findings in the present study, the  
372 spreading of *Ochrobactrum* sp. was seemingly not affected. Although the metagenomes in  
373 the present study contained an abundant essential genes for degrading a variety of aromatic  
374 compounds, the microbial degradation of these compounds might have been attenuated by  
375 a lack of oxygen and a high level of salinity<sup>61</sup>. Anaerobic degradation of compounds is  
376 more difficult than aerobic degradation, often requiring oxygen donors such as nitrate and  
377 sulfate<sup>59,60</sup>. Based on its ability to survive under anoxic conditions, *Ochrobactrum* sp. is  
378 probably able to maintain a higher level of fitness in the control sediment compared with  
379 *Alcanivorax*. In the present study, the *Alkanindiges* identified in both metagenomes was  
380 also a well-known alkane degrader<sup>62,63</sup>. Because of its presence in both anhydrites and the  
381 adjacent sulfide layer, we assumed that the *Alkanindiges* bacterium was also capable of  
382 surviving aerobically and anaerobically in the oil-producing sediment. Hence, the change  
383 from an oxic to an anoxic benthic environment caused a dramatic shift in the microbial  
384 communities, resulting in the extinction of the obligate aerobic alkane-utilizer *Alcanivorax*  
385 and continuous residency of anaerobic oil-degraders. The availability of nitrogen oxides  
386 and the dissolution of sulfate from anhydrite crystals were possibly critical to the metabolic  
387 activities of the anaerobes. In addition, the *Bacillus* and fungi present in the control  
388 sediment were probably present in the form of dormant spores. In a recent report,

389 *Ochrobactrum* and *Bacillus* were confirmed to be dominant species in some upper sulfide  
390 layers in the Atlantis II<sup>53</sup>. Altogether, in the present study, the current microbial inhabitants  
391 in the sulfide layers were largely different from those in the anhydrite crystals.

392

393 The geochemical data collected herein suggested that the sub-superficial anhydrite layer  
394 could release organic carbon contents into the sediment, as reported previously<sup>12,13</sup>. Our  
395 measurement of DOC at 80.9 mg L<sup>-1</sup> in the anhydrite layer was higher than the generally  
396 accepted maximum value of 50 mg L<sup>-1</sup> for marine sediments<sup>64</sup>. The abnormally high DOC  
397 was considered a notable alteration of the local environments, probably resulted from the  
398 breakdown of anhydrite crystals. Anhydrites in the Atlantis II brine sediment were likely  
399 maintained by the high salinity and temperature, and then slowly dissolved. This  
400 phenomenon may be explained by the slight undersaturation of the anhydrite in the Atlantis  
401 II sediment<sup>17</sup>. Such anhydrite layers are widely distributed in Middle Eastern sediments<sup>65</sup>.  
402 Hence, our findings shed light on the formation of micro-environments by anhydrite  
403 evaporites in the deep sediments. In this study, there was an inconsistency between the cell  
404 density and the DOC at the 12-cm depth layer, in which the DOC could not support a 10-  
405 fold higher biomass. This phenomenon probably resulted from the formation of petroleum  
406 compounds under the hydrothermal effects<sup>50</sup>. In the petroleum, hydrophobic organic  
407 compounds (HOCs) consisting of polycyclic aromatic hydrocarbons (PAHs) could not be  
408 counted in our DOC measurements (personal communication with J. Pearsons). The  
409 nutrient supply is critical for microbes to survive in deep-sea sediment. Apart from the  
410 chemolithoautotrophic microbes, numerous other inhabitants take advantage of the buried  
411 organic matter. Importantly, the trapped organic matter serves as a nutrient supply  
412 following the dissolution of organic-rich anhydrite crystals. Therefore, our findings  
413 highlighted the importance of the nutrients released from the anhydrite facies for microbes  
414 in deep-sea subsuperficial sediment.

415

416 **Author contributions.** Y. Wang, T.G. Li, and P. Y. Qian were responsible for the study  
417 design. Data analysis was performed by Y. Wang, T.G. Li, J. T. Li, Q. L. Lai, and Z. M.  
418 Gao. M.Y. Wang conducted FISH assay. The manuscript was prepared by Y. Wang with  
419 contributions from all co-authors.

609 **Data Accessibility**

610 Illumina raw data will be accessible under SRA356974 in the NCBI SRA database. *B.*

611 *borkumensis* ABS183 genome was deposited in the NCBI under BioProject

612 LKAP00000000 and will be public on October 31, 2016.

613

614

615 **Table 1.** Age estimates of the sediment layers

Layer (cm)	Age (year)	Age error (year)
3-6	320	25
21-24	475	35
45-48	490	30
90-93	500	25
129-132	560	35
153-156	750	30
198-201	770	30
222-225	880	30

616

617 Eight sediment layers were selected for the age estimates using radioisotope  $^{14}\text{C}$  of *G.*

618 *sacculifer* collected from the respective layers. The age was corrected by the 400-year

619 reservoir age with an error range.

620

621

622 **Figures**

623 **Figure 1. Anhydrite crystals and genome binning.**

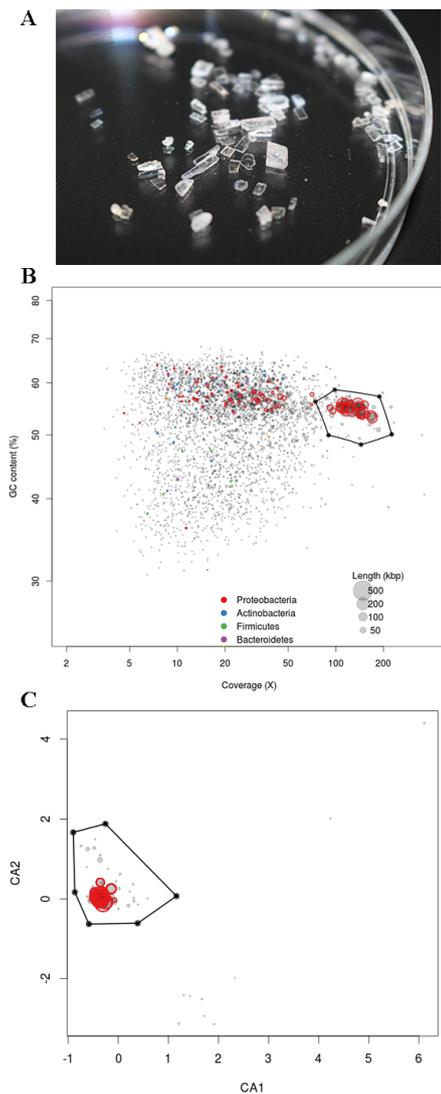

624 Anhydrite crystals in a Petri dish (90 mm in diameter) (A) were used for DNA extraction.

625 The amplified genomic DNA was sequenced and then reassembled. Based on the G+C

626 content and read coverage, the binned contigs with high coverage levels (B) were

627 selected for examination of the tetranucleotide frequency consistency in the PCA analysis

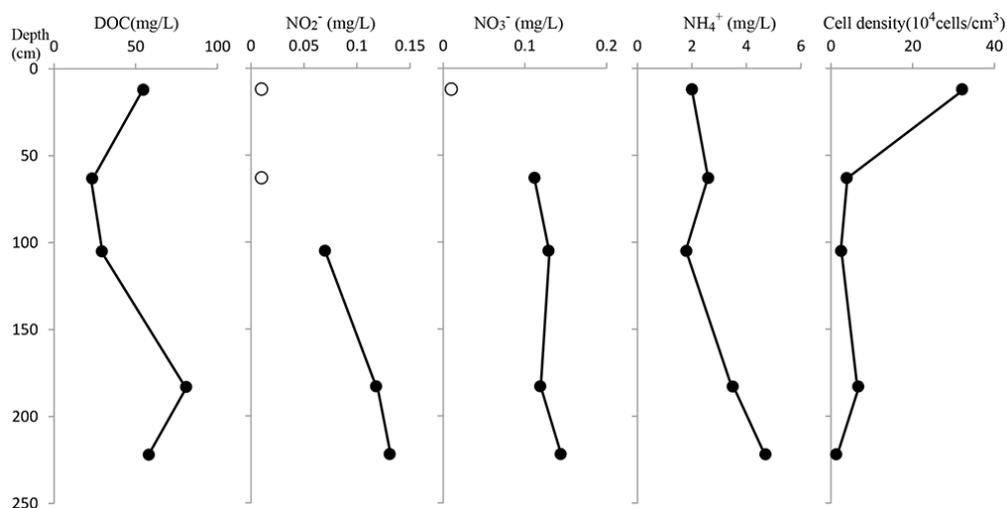

628 (C).

629

630 **Figure 2. Nutrient measurements and cell counts in the different sediment layers.**  
631 The pore water samples were analyzed for five layers of a sediment core obtained from  
632 the Atlantis II Deep (21°20.76' N, 38°04.68' E) in 2008. DOC: dissolved organic carbon.

651 **Figure 3 Grain size and age of selected layers**

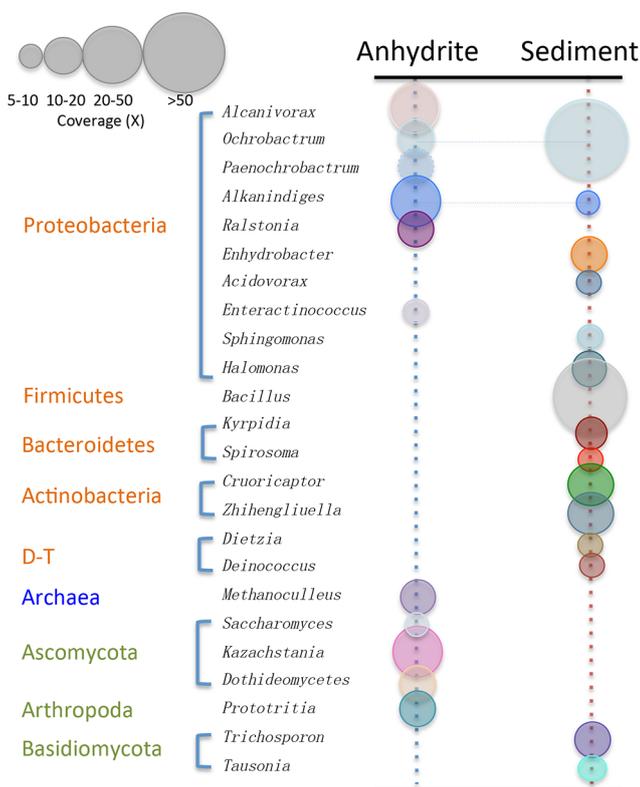

652 The percentages of the small particles (<63µm) in dry weight are shown for 75 slices of  
653 the sediment core (small squares on the line). The age estimates (black circles) of the  
654 selected layers were performed using radioisotope <sup>14</sup>C of the  
655 monospecific *Globigerinoides sacculifer* specimens. Age errors ranged between 25 to 40  
656 years. Anhydrite and control layers for metagenomic study were indicated by arrows.

660

661 **Figure 4. Microbial communities in anhydrite crystals and neighboring control**  
 662 **sediment.**  
 663 Phyla and genera in the anhydrite crystals and control layer were predicted using 16S/18S  
 664 rRNA gene fragments extracted from the corresponding metagenomes (D-T: Deinococcus-  
 665 Thermus). The relative abundance of the genera can be estimated by the coverage level of  
 666 the 16S/18S rRNA fragments by reads.

698 **Figure 6. Fluorescence *in situ* hybridization (FISH) of *Alcanivorax* sp. ABS183**  
699 **embedded in anhydrite crystals.**

700 DAPI staining and FISH using 16S rRNA probes are shown in A and B. The merged image  
701 of A and B is shown in Fig. 6C. DAPI staining and FISH were also performed using two  
702 samples that were filtered with 3- $\mu\text{m}$  (D-G) and 0.22- $\mu\text{m}$  (H-K) membranes, respectively.  
703 *Alcanivorax* bacteria were released from the large crystals filtered through the 3- $\mu\text{m}$   
704 membranes (D-G). The bacteria were stained with DAPI (D), 16S rRNA probes (E) and  
705 the *alkB* probe (F), respectively, and overlaid (G). Using a sample filtered through a 0.22-  
706  $\mu\text{m}$  membrane, a dividing *Alcanivorax* sp. ABS183 cell was labeled using the same method  
707 and probes (H-J). The microscopic fields shown in H-J are merged in Fig. 6K.
