Sources and Transformations of Anthropogenic Nitrogen along an Urban River-1
Estuarine Continuum

Abstract

Urbanization has altered the fate and transport of anthropogenic nitrogen (N) in rivers and estuaries globally. This study evaluates the capacity of an urbanizing river-estuarine continuum to transform N inputs from the world’s largest advanced (e.g. phosphorus and biological N removal) wastewater treatment facility. Effluent samples and surface water were collected monthly along the Potomac River Estuary from Washington D.C. to the Chesapeake Bay over 150 km. In conjunction with box model mass balances, nitrate stable isotopes and mixing models were used to trace the fate of urban wastewater nitrate. Nitrate concentrations and δ^{15}N-NO_3^- values were higher down-estuary from the Blue Plains wastewater outfall in Washington D.C. (2.25±0.62 mg/l and 25.7±2.9‰, respectively) compared to upper-estuary concentrations (1.0±0.2 mg/l and 9.3±1.4‰, respectively). Nitrate concentration then decreased rapidly within 30 km down-estuary (to 0.8±0.2 mg/l) corresponding with an increase in organic nitrogen and dissolved organic carbon, suggesting biotic uptake and organic transformation. TN loads declined down-estuary (from an annual average of 48,000±5,000 kg/day at the sewage treatment plant outfall to 23,000±13,000 kg/day at the estuary mouth), with the greatest percentage decrease during summer and fall. 4–71% of urban wastewater TN inputs were exported to the Chesapeake Bay, with the greatest contribution of wastewater TN loads during the spring. Our results suggest that biological transformations along the urban river-estuary continuum can significantly transform wastewater N inputs from major cities globally, but more work is necessary to evaluate the potential of organic nitrogen to contribute to eutrophication and hypoxia.
1 Introduction

Urbanization and agriculture have greatly increased the exports of nitrogen from coastal rivers and estuaries globally, contributing to eutrophication, hypoxia, harmful algal blooms, and fish kills (e.g. Aitkenhead-Peterson et al., 2009; Kaushal et al., 2014b; Nixon et al., 1996; Petrone, 2010; Vitousek et al., 1997). Despite billions of dollars spent on regulatory and technological improvements for wastewater treatment plants (WWTPs) and agricultural and urban stormwater runoff (e.g. US-EPA, 1972, 2009, 2011), many coastal waters are still impaired. Also, there are major questions regarding how far urban sources of N (wastewater and stormwater runoff) are transmitted along tidal river-estuarine networks to N-sensitive coastal receiving waters. This study evaluates the capacity of a major river-estuarine system to transform and attenuate N inputs from the world’s largest advanced (e.g. phosphorus and biological nitrogen removal) wastewater treatment plant (Blue Plains) before being transported down-estuary to the Chesapeake Bay. We used a combination of stable isotope and box model mass balance approaches to track the fate and transport of anthropogenic nitrogen across space and time.

In addition to urban and agricultural inputs, altered river-estuarine hydrology can contribute to higher exports of N. Jordan et al. (2003) found that annual water discharge increased as the proportion of developed land in a coastal watershed increased. Higher flows, typically during winter and spring months, have also been associated with higher N loads in coastal river-estuaries (Boynton et al., 2008). Furthermore, regional climate
variability amplifies pulses of nutrients and other contaminants in rivers (Easterling et al., 2000; IPCC, 2007; Kaushal et al., 2010b; Saunders and Lea, 2008) and alters the biotic transformation of N due to changes in hydrologic residence times (Hopkinson and Vallino, 1995; Kaushal et al., 2014b; Wiegert and Penaslado, 1995). For example, high flow periods related to storms can induce stratification and impact salinity regimes (Boesch et al., 2001), which affects nutrient biogeochemistry like ammonium and phosphate concentrations (Jordan et al., 2008). An improved understanding of the longitudinal assimilatory capacity for nitrogen by large river-estuarine systems across different flow regimes is needed for guiding effective coastal river and estuarine management strategies.

One critical and innovative approach to effectively manage coastal nutrient pollution is to 1) track the relative contributions of N export from different sources within the watershed and 2) understand the potential for longitudinal transformation within coastal rivers and estuaries. Recent studies using stable isotopes (Kaushal et al., 2011; Kendall et al., 2007; Oczkowski et al., 2008; Wankel et al., 2006) have shown that these methods can be helpful in elucidating sources and transformations of nitrogen. However, these studies are typically conducted at relatively smaller spatial scales and without coupling to mass balance approaches over both time and space.

Here, we combine isotope and mass balance approaches to track sources and transformations of urban wastewater inputs to Chesapeake Bay over space and time across an urban river-estuary continuum spanning over 150 km. The space-time continuum approach has previously been used in studying fate and transport of carbon and nitrogen in urban watersheds (Kaushal and Belt, 2012; Kaushal et al., 2014c), and
here we explore extending it to river and estuarine ecosystems. Our overarching questions were: 1) how does the importance of point vs. non-point sources of N shift along a tidal and stratified urban river-estuary continuum across space and time? 2) What is the capacity of an urban river-estuary continuum to transform or assimilate anthropogenic N inputs? 3) How are transport and transformations of N affected by differences in season or hydrology? An improved understanding of how sources and transformations of N change along the urban river-estuarine continuum over space and time can inform management decisions regarding N source reductions along urbanizing coastal watersheds (e.g. Boesch et al., 2001; Kaushal and Belt, 2012; Paerl et al., 2006).

2 Methods

2.1 Site Description

This study is focused on the tidal Potomac River Estuary, which includes the section of the river from Washington D.C. to its confluence with the Chesapeake Bay (Fig. 1). The Potomac River Estuary begins as tidal freshwater, becoming oligohaline ~30-50 km below Washington D.C., and mesohaline at its mouth approximately 160 km below Washington D.C. (Jaworski et al., 1992). The Potomac River Estuary can be seasonally stratified (Hamdan and Jonas, 2006), especially in the southern portion of the system where intruding, saline bottom water from the main stem of the Chesapeake Bay leads to density driven estuarine circulation patterns (Elliott, 1976, 1978; Pritchard, 1956). Mixing is most evident at the estuarine turbidity maximum (Hamdan and Jonas, 2006), ~60-80 km below Washington D.C., and the water column is generally well mixed above the estuarine turbidity maximum zone in the tidal fresh and oligohaline regions of.
the estuary (Crump and Baross, 1996; Sanford et al., 2001).

The watershed draining to the Potomac River Estuary is classified as 58% forested, 23% agricultural, and 17% urban, based on Maryland Department of Planning data for 2002 (Karrh et al., 2007a). Based on the Chesapeake Bay Program (CBP) Model it was estimated that during 2005 total inputs of nitrogen were 33% from agriculture, 20% from urban (e.g. stormwater runoff and leaky sewers), 19% from point sources (wastewater treatment plants and industrial releases), 11% from forest, 10% from septic, 6% from mixed open land, and 1% from atmospheric deposition to water (Karrh et al., 2007b).

The CBP model is developed using long-term monitoring data and the non-point loads are estimated from a variety of sources including land cover and agriculture records (Karrh et al., 2007b). The Potomac River Estuary also receives N inputs from Blue Plains wastewater treatment plant, located in Washington, D.C. Blue Plains currently discharges 2.3 mg/L of NO$_3^-$ and 3.7 mg/L of TN, on average, and exports loads of approximately 2,300 kg/day of NO$_3^-$ and 3,900 kg of TN. Overall, Blue Plains treats and discharges 280 million gallons per day (mgd), almost 5% of Potomac River's annual discharge. In the past several decades, Blue Plains has undergone several technological improvements with phosphorus removal in the 1980s and enhanced N removal beginning in the year 2000. Since the implementation of advanced wastewater treatment technologies at Blue Plains, there has been a significant decrease ($p < 0.01$) in the concentration of nitrate in effluent discharge, from an average of $7.2 \pm 0.3$ mg/L before the year 2000 (years 1998 and 1999) to an average of $4.1 \pm 0.4$ mg/L after 2000 (years 2001 to 2008).
2.2 Analysis of long-term spatial and temporal water chemistry data

Surface and bottom water N and carbon data collected by the Maryland Department of Natural Resources (DNR) and accessed through the Chesapeake Bay Program’s data hub website (Chesapeake Bay Program, 2013) was used to look at historical (1984 to 2012) monthly nutrient concentrations from stations located longitudinally along the Potomac River Estuary (Fig. 1). These data were used to look at the spatial and temporal trends for dissolved and particulate forms of N and dissolved organic carbon (DOC) in the Potomac River Estuary prior to and during this study.

2.3 Water Sampling

Water samples along the Potomac River estuary were collected monthly for one year from April 2010 to May 2011; from 12 km to 160 km below the Blue Plains wastewater treatment plant (See Fig. 1). Water was collected from the surface (top 0.5 m) and bottom water depths. Additionally, surface water samplings from 6 km above to 12 km below the Blue Plains wastewater treatment plant effluent outfall were collected seasonally during this time (Fig. 1). Water temperature and salinity was also measured during each water sampling.

2.4 Nitrate δ¹⁵N and δ¹⁸O Isotope Analysis

Surface samples for δ¹⁵N-NO₃⁻ and δ¹⁸O-NO₃⁻ isotopes of dissolved nitrate were filtered (0.45 μm), frozen, and shipped to the UC Davis Stable Isotope Facility (SIF) for analysis. The isotope composition of nitrate was measured following the denitrifier method (Casciotti et al., 2002; Sigman et al., 2001). In brief, denitrifying bacteria are
used to convert nitrate in samples to N$_2$O gas, which is collected and sent through a mass spectrometer for determination of the stable isotopic ratios for N and O of nitrate ($^{15}$N/$^{14}$N and $^{18}$O/$^{16}$O). Values for $\delta^{15}$N-NO$_3^-$ and $\delta^{18}$O-NO$_3^-$ are reported as per mil (‰) relative to atmospheric N$_2$ ($\delta^{15}$N) or Vienna Standard Mean Ocean Water (VSMOW) ($\delta^{18}$O), according to $\delta^{15}$N or $\delta^{18}$O (‰) = [(R)$_{\text{sample}}$ / (R)$_{\text{standard}}$ - 1] $\times$ 1000, where R denotes the ratio of the heavy to light isotope ($^{15}$N/$^{14}$N or $^{18}$O/$^{16}$O). For data correction and calibration UC Davis SIF uses calibration nitrate standards (USGS 32, USGS 34, and USGS 35) supplied by NIST (National Institute of Standards and Technology, Gaithersburg, MD). The long-term standard deviation for nitrate isotope samples at UC Davis SIF is 0.4 ‰ for $\delta^{15}$N-NO$_3^-$ and 0.5 ‰ for $\delta^{18}$O-NO$_3^-$. Previous studies (Kaushal et al., 2011; Kendall et al., 2007) indicate that the relative amounts of $\delta^{15}$N-NO$_3^-$ and $\delta^{18}$O-NO$_3^-$ can be used to determine specific sources of nitrate (i.e. fertilizer, nitrification, atmospheric, or sewage derived nitrate).

It should be noted that while the denitrifier method converts sample NO$_3^-$ and NO$_2^-$ to N$_2$O gas, in marine systems, NO$_2^-$ has been shown to complicate interpretations of the N and O isotopes of NO$_3^-$ if it remains unaccounted for (e.g. Fawcett et al., 2015; Marconi et al., 2015; Rafter et al., 2013; Smart et al., 2015). This is partially because during the reduction of NO$_3^-$ and NO$_2^-$ to N$_2$O by the denitrifiers, the O isotope effects are different (and thus need to be corrected for). In addition, the $\delta^{15}$N of NO$_2^-$ can be extremely different from that of NO$_3^-$, potentially further complicating interpretation of the data.
To distinguish between the different potential nitrate sources we used a Bayesian isotope mixing model (Parnell et al., 2010; Parnell et al., 2013; Xue et al., 2012; Yang and Toor, 2016). For the Bayesian isotope mixing model, the Stable Isotope Analysis in R (SIAR) package was used to determine the fraction of nitrate in each sample from four different sources: wastewater, atmospheric, nitrification, and nitrate fertilizer (Parnell et al., 2010; Parnell et al., 2013; Xue et al., 2012; Yang and Toor, 2016). The SIAR mixing model is able to incorporate uncertainty in nitrate source estimates based on the uncertainty in the nitrate source endmembers (see below) (Parnell et al., 2010; Parnell et al., 2013; Xue et al., 2012; Yang and Toor, 2016).

Nitrate source end-member values, for $\delta^{15}$N-$\text{NO}_3^-$ and $\delta^{18}$O-$\text{NO}_3^-$, were obtained from the literature, except wastewater nitrate, which was obtained from this study. The end-member values for $\delta^{15}$N-$\text{NO}_3^-$ and $\delta^{18}$O-$\text{NO}_3^-$ were -10.3±1.7 and 10.1±1.5, respectively for nitrate from nitrification (Mayer et al., 2001), 0±3 and 22±3, respectively for NO$_3^-$ fertilizer (Mayer et al., 2002), and 3±3 and 69±5, respectively for atmospheric nitrate (Burns and Kendall, 2002; Divers et al., 2014). The wastewater $\delta^{15}$N-$\text{NO}_3^-$ and $\delta^{18}$O-$\text{NO}_3^-$ end-member values (31.5±7.8 and 11±4.5, respectively) were based on averaging the effluent nitrate isotope values measured monthly from Blue Plains during the study period. The nitrification source represents NO$_3^-$ from nitrification in the water as well as nitrification of ammonia fertilizer in the watershed. The fertilizer source represents synthetically produced NO$_3^-$ fertilizer, not the more common ammonia fertilizer.
Due to the variability in nitrate source endmembers, the mixing model was used primarily for illustrative purposes and should be viewed with caution (particularly with regard to identifying other sources besides wastewater). For example, there is high variability in the nitrification source endmembers because nitrate from nitrification can come from ammonia fertilizer, manure fertilizer, particulate organic matter within the water column, etc. The nitrate from nitrification will therefore carry a range of nitrate isotope values reflecting its original source (Kendall et al., 2007). Additionally, because denitrification is known to cause the increase in $\delta^{15}$N-NO$_3^-$ and $\delta^{18}$O-NO$_3^-$ values through isotopic fractionation in approximately a 2:1 relationship (Divers et al., 2014; Kendall et al., 2007), this isotopic enrichment can complicate the identification of wastewater nitrate. As a result, water samples with increased wastewater nitrate, based on the mixing model, may also suggest denitrification has played a role in the isotopic levels of the sample nitrate.

2.6 Salinity vs. Nitrate Concentration and Isotope Mixing Plots

An additional method using plots of salinity vs. NO$_3^-$ concentration or NO$_3^-$ isotopes was used to assess whether there is conservative mixing (dilution), or mixing with additional NO$_3^-$ sources down-estuary, or losses of NO$_3^-$ through biotic uptake or denitrification (Middelburg and Nieuwenhuize, 2001; Wankel et al., 2006). Mixing line equations for NO$_3^-$ concentrations were based on equations 1-3 from Middelburg and Nieuwenhuize (2001) and isotopes mixing lines were based on equation 4 from Middelburg and Nieuwenhuize (2001). The mixing line equations and endmember values used for salinity and nitrate isotopes are provided in supporting information (Table
Based on those equations, the salinity vs. NO$_3^-$ concentration mixing lines are linear, while the mixing lines for NO$_3^-$ isotopes are non-linear (Middelburg and Nieuwenhuize, 2001). Wankel et al. (2006) suggests that when nutrient concentrations fall above the mixing line this indicates an additional source to raise the concentrations, while concentrations that fall below the mixing line indicate there is a nutrient sink (e.g., denitrification, assimilation, etc.). For nitrate isotopes, when the $\delta^{15}$N-NO$_3^-$ and $\delta^{18}$O-NO$_3^-$ values fall above this mixing line, this could indicate an additional source or the fractionation of nitrate from assimilation or denitrification that would increase the heavy isotope levels, while isotope values below the mixing line could indicate an additional source of nitrate with lighter isotope values, such as from nitrification or fertilizer sources (Wankel et al., 2006).

### 2.7 Estuarine Nitrogen Net Fluxes

A box model was used to estimate net fluxes of TN, NO$_3^-$, and nitrate isotope loads along the Potomac River Estuary using methods modified from Officer (1980), Boynton et al. (1995), Hagy et al. (2000), and Testa et al. (2008), which are widely used methods for tracking nutrient fluxes in estuaries between different salinity zones. First, the Potomac Estuary was divided into 6 boxes in order to accommodate adequate sampling stations per box, and to evaluate net fluxes at key locations along the estuarine gradient (Fig. 2). Next, due to the Potomac Estuary having a semi-diurnal tidal cycle, where there is movement back and forth across boundaries of the box model, mean monthly freshwater discharge inputs to the first box (USGS, 2014) and interpolated salinity values (measured monthly from surface and bottom waters throughout the
system) were used to calculate advective and diffusive exchanges of water and salt between adjacent boxes. Salt balances were then used to compute net exchanges at the boundaries of the six model boxes, similar to previous estuarine box model studies (e.g. Boynton et al., 1995; Hagy et al., 2000). Average monthly TN, NO$_3^-$ and NO$_2^-$ isotope concentrations (collected from the surface and bottom water at each station, except for NO$_3^-$ isotopes, which were collected from the surface only) were multiplied by net estimated exchange values at the box boundaries and summed to calculate the N load leaving or entering each box. In order to calculate the loads for NO$_3^-$ isotopes, the $\delta^{15}$N-NO$_3^-$ and $\delta^{18}$O-NO$_3^-$ values in per mil (‰) were converted to concentrations (µg/L) by multiplying the NO$_3^-$ concentration of the sample by R, the ratio of the heavy to light isotope ($^{15}$N/$^{14}$N or $^{18}$O/$^{16}$O). Fluxes were estimated for each month during the sampling period and then averaged to find seasonal estimates of N fluxes for the Potomac. The box model results were used to compute: (1) the total inputs of N, (2) the % inputs of loads from Blue Plains, (3) the net export of N to the Chesapeake Bay, (4) the % of Blue Plains inputs that are exported, (5) the net loss in loads along the estuary, and (6) the contribution of N loads from the Chesapeake Bay through tidal inflow.

To account for uncertainty in monthly load estimates, error propagation was used for each of the hydrologic and nutrient inputs to the model. For example, the error in discharge data came from averaging the mean daily discharge for each month, the error in water concentrations came from averaging the surface and bottom water concentrations, and the error in N from atmospheric deposition came from averaging the weakly deposition data for each month. These uncertainties in the inputs to the box model were
then propagated for each of the box model calculations, similar to Filoso and Palmer (2011).

Inputs to the box model include, total monthly precipitation data based on averaging data from three stations along the Potomac Estuary (Precipitation data is from the NOAA National Centers for Environmental Information, Climate Data Online), monthly estimates of atmospheric deposition for NH$_4^+$, NO$_3^-$, and DIN (obtained from the National Atmospheric Deposition Program / National Trends Network), NO$_3^-$ concentrations and isotope levels in atmospheric deposition (from Buda and DeWalle, 2009, for the nearby central Pennsylvania region for the year 2005, which was a similar year hydrologically (as described below)), N inputs from the land (from Chesapeake Bay model output from 2005), surface and bottom water nutrient and salinity concentrations (from MD DNR), and inputs from the Blue Plains wastewater treatment plant. Also, while there are no USGS gages located along the Potomac Estuary, there is one USGS gage (USGS 01646580) located directly above the Estuary, above the fall line (the location where the hydrodynamics of the river cease being tidally influenced) and this gage was used to account for freshwater inputs into the first box. The model also takes into account water temperature and evaporation.

For the box model it is assumed that the 14 other WWTPs further down-estuary have little effect on the nitrate signal because their combined TN load is 32% of the TN from Blue Plains and for the other reasons described below. While $\delta^{15}$N-NO$_3^-$ and $\delta^{18}$O-NO$_3^-$ isotope values were not measured directly for the 14 other down-estuary wastewater treatment plants, based on the literature, the values of these isotopes are typically lower ($-10\%$ for $\delta^{15}$N-NO$_3^-$ and $-0$ for $\delta^{18}$O-NO$_3^-$) compared to $31.5\%$ for $\delta^{15}$N-NO$_3^-$ and
11‰ $\delta^{18}O-\text{NO}_3^-$ for Blue Plains (Kendall et al., 2007; Wang et al., 2013; Wankel et al., 2006). As a result, we expected the other WWTPs to have a similar or an even less pronounced wastewater isotope signal compared to Blue Plains, which has biological nitrogen removal (i.e. denitrification is promoted within the WWTP), elevating the $\delta^{15}N-$NO$_3^-$ and $\delta^{18}O-$NO$_3^-$ isotope values at Blue Plains more (Kendall et al., 2007).

Consequently, the estimated nitrate loads down-estuary incorporate Blue Plains and nitrate inputs from the other WWTPs, and are considered conservative estimates because the additional WWTPs only add to the TN loads and NO$_3^-$ isotope signals and thus lessen the decline in loads or isotope values down estuary.

A second assumption was made for the box model related to estuarine mixing. Although portions of the lower estuary can be seasonally stratified, we assumed each box to be well mixed vertically as no bottom water isotope values were available to constrain a 2-layer box model. This assumption is supported by other bottom water data that is available and by samples taken along the width of the estuary. For example, we have conducted the box model and other analyses with and without bottom water isotope data and found minimal change in results (Fig. S1, see below). Our measurements of various biogeochemical signatures at the station close to the estuarine turbidity maximum suggests that there is intense mixing at this site, and prior studies have documented extensive mixing in the freshwater tidal portion of the system (Elliott, 1976, 1978; Pritchard, 1956). Also, it can be assumed that because wastewater effluent inputs are freshwater, much of the effluent plume would likely not sink in the more dense estuarine waters moving up from the bay. Additionally, our box model estimates of net fluxes was compared to a complex, 3 dimensional hydrodynamic model (described below) that
incorporates stratification, and this comparison provided support for the low impact of
assuming mixing in our approach.

While seasonal stratification has been found close to the mouth of the Potomac estuary
(Hamdan and Jonas, 2006), using documented nitrate bottom water isotope values from near the mouth of the estuary (Horrigan et al., 1990) we calculate that incorporating bottom water isotope values would have a minimal impact on the flux estimates of our box model, particularly when not including spring 2011 (Fig. S1). But when including spring 2011, and using the reported values of 10‰ for bottom water δ15N-NO3, based on Horrigan et al. (1990), in Boxes 5 and 6 where stratification is most likely, our estimates for the flux of δ15N-NO3 from these boxes increases by 20% on average, and the net loss in load from box 1 to box 6 increases by 12% on average. This indicates that our estimates are conservative because by not using bottom water we estimate a smaller net loss in δ15N-NO3 (Fig. S1).

For the box model we also assumed the estuary to be well mixed laterally. In terms of potential variability for samples taken at different locations along the width of the estuary, there was found for surface water samples, on average, a 6±3% difference in δ15N-NO3, a 7±3% difference in δ18O-NO3, a 24±8% difference in NO3, and a 15±3% difference in TN (based on samplings that were done at two or more locations along the same longitudinal transect at approximately the same distance down-estuary, but at different locations horizontally at that location). Based on this, the nitrate isotopes values and NO3 and TN concentrations appear to show that the estuary is fairly well mixed laterally.
To assess the accuracy of the box model assumptions and results, estimated net fluxes of total N were compared to simulation output from the Chesapeake Bay Water Quality Model. This model was developed by the U.S. EPA to aid in efforts to set TMDLs for the Chesapeake Bay (Cerco et al., 2010), and combines a 3-D hydrodynamic model (CH3D) with a water quality model (CE-QUAL-ICM). Simulation output data were available for 1996, 2002, and 2005. We selected a simulation year (2005) because it had similar river discharge conditions to 2010, and compared modeled net fluxes of TN at three boundary locations to estimates at the same (or nearby) box model boundaries.

2.8 Statistical Analyses

Statistical analyses were performed using the statistical package R (R Development Core Team, 2013). Linear regression was used to test for significant changes in stream chemistry and nitrate isotope data with distance down estuary. Repeated measures analysis of variance (ANOVA) was used to test for seasonal differences in nitrate isotopes trends with distance.

3 Results

3.1 Spatial and Temporal Trends in N Concentrations

Longitudinal patterns of dissolved inorganic nitrogen (DIN) in the lower Potomac River showed an increase in concentrations near and directly below the Blue Plains wastewater treatment plant and then a steady decline in concentrations down to the Chesapeake Bay (Fig. 3a). The implementation of tertiary treatment in 2000 coincided with a significant drop in annual average DIN concentration directly down-estuary (from
1.7 ± 0.02 to 1.3 ± 0.01 mg/l, p < 0.05) (Fig. 3a), when comparing years directly prior (1997-1999) and the years directly after 2000 (2001-2005). However, the impact of the wastewater treatment plant improvements on reducing longitudinal patterns of DIN was only apparent for the first 30 km down-estuary. After this, both the pre- and post-2000 DIN concentrations overlapped (Fig. 3a). As DIN decreased longitudinally down-estuary of the wastewater treatment plant, there was also a small, but significant increase in total organic nitrogen (TON) after the year 2000 (p < 0.01, Fig. 3a), not including the last sample near the mouth of the estuary, which is likely influenced by tidal inflow.

There were seasonal variations in DIN concentrations along the Potomac River Estuary with the greatest concentrations in the winter and spring (Fig. 3b). There is also a steeper decline in DIN with distance during fall, winter, and summer compared to the spring (p < 0.05, Fig. 3b). The average molar ratio of DIN to PO$_4^{3-}$ (N:P ratio) showed an initial increase, then a decrease as estuarine salinity started to increase (Fig. 3c).

During the summer and fall, the N:P ratio fell below the Redfield ratio (16:1, the atomic ratio of nitrogen and phosphorus found in oceans and phytoplankton), around 40 km down-estuary and stayed below 16, which indicated a shift from P to N limitation.

During the winter and spring, the N:P ratio never fell below 16 and increased steadily after 50 km down-estuary (Fig. 3c). There was also a significant negative relationship between NO$_3^-$ and DOC concentration during the study period (p < 0.01, Fig. 4).

3.2 Spatial and Seasonal Trends in NO$_3^-$ Isotopes and Sources

During each season, except spring, $\delta^{15}$N-NO$_3^-$ values increased sharply at the Blue Plains outfall, from 9.3 ± 1.4 ‰ up-estuary to 25.7 ± 2.9 ‰ at the outfall (p < 0.05),
and then rapidly decreased within 2 km down-estuary to 15.7 ± 2.2 ‰ (p < 0.05, Fig. 5a).

During the summer and fall, the δ¹⁵N-NO₃⁻ values showed the largest increase near the effluent outfall (except for one very high winter value) and then a significant decrease (p < 0.05) with distance down-estuary. There was also a slight increase in δ¹⁵N-NO₃⁻ and δ¹⁸O-NO₃⁻ values from 1 to 6 km down-estuary (Fig. 5a,b). During the winter and spring, the δ¹⁵N-NO₃⁻ and δ¹⁸O-NO₃⁻ values remained relatively constant throughout the estuary, even near Blue Plains (Fig. 5a,b), while during the summer and fall the δ¹⁵N-NO₃⁻ and δ¹⁸O-NO₃⁻ values steadily declined after 6-10 km down-estuary (Fig. 5a,b). At the mouth of the estuary, the δ¹⁵N-NO₃⁻ values for all seasons were roughly equivalent (Fig. 5a).

During the summer and fall, the δ¹⁸O-NO₃⁻ values showed a steady decrease after 12 km down-estuary, while they increased during spring and winter (Fig. 5b).

Based on the nitrate isotope mixing model, nitrate contributions from wastewater ranged from 80 ± 13% at the wastewater outfall to 57 ± 11% within the first 1 km down-estuary. Wastewater nitrate contributions then decreased to 44 ± 14% at the confluence of the Potomac River Estuary with Chesapeake Bay (Fig. 5c). Nitrate from nitrification (of N from upriver manure or ammonia fertilizer and also Blue Plains wastewater N) increased from 13 ± 12% at the wastewater outfall to 29 ± 22% at the confluence of the Potomac River Estuary with Chesapeake Bay (Fig. 5c). Nitrate from fertilizer increased from 6 ± 6% at the wastewater outfall to 22 ± 22% at the confluence of the Potomac River Estuary with Chesapeake Bay (Fig. 5c). Nitrate from atmospheric deposition changed little along the Potomac Estuary from 1 ± 1 at the wastewater outfall to 5 ± 5 at the confluence with the Chesapeake Bay (Fig. 5c).
the mouth of the Potomac River Estuary, NO$_3^-$ from fertilizer showed an increase, while NO$_3^-$ from nitrification showed a corresponding decline (Fig. 5c).

3.3 $\delta^{15}$N-NO$_3^-$ and $\delta^{18}$O-NO$_3^-$, NO$_3^-$ Concentration, and Salinity Relationships

The Blue Plains effluent and Potomac River samples within 20 km downriver of the wastewater treatment plant showed a significant positive relationship between $\delta^{15}$N-NO$_3^-$ and $\delta^{18}$O-NO$_3^-$ ($p < 0.05$) (Fig. 6a). When denitrification and biotic uptake occurs, plotting $\delta^{15}$N-NO$_3^-$ vs. $\delta^{18}$O-NO$_3^-$ shows a 2:1 relationship (Kendall et al. 2007). The Blue Plains effluent samples showed approximately a 2.4 to 1 relationship. The samples within 20 km downriver showed a 3:1 ratio (Fig. 6a). The nitrate samples within the first 6 km showed a 2.4 to 1 relationship (Fig. 6a). There were also seasonal differences in the relationship between $\delta^{15}$N-NO$_3^-$ and $\delta^{18}$O-NO$_3^-$ (Fig. 6b); spring, summer, and fall were characterized by close to a 2:1 relationship between $\delta^{15}$N-NO$_3^-$ vs. $\delta^{18}$O-NO$_3^-$, while winter showed a ~8:1 relationship.

Because salinity is a conservative tracer, plots of salinity vs. NO$_3^-$, $\delta^{15}$N-NO$_3^-$, and $\delta^{18}$O-NO$_3^-$ can indicate effects of mixing between water at the tidal freshwater section with water from the mesohaline section of the Potomac River Estuary. Deviations from the mixing lines can indicate additional sources or biological transformations (Middelburg and Nieuwenhuize, 2000; Wankel et al., 2006). Surface water NO$_3^-$ concentrations and nitrate isotopes fell on (for $\delta^{18}$O-NO$_3^-$) or slightly below mixing line (for $\delta^{15}$N-NO$_3^-$) during the spring (Fig. 7a,b,c), which indicated mostly conservative mixing (dilution or inputs from low $\delta^{15}$N-NO$_3^-$ like nitrification, see discussion below). But during the summer and fall, the NO$_3^-$ concentration and isotope values fell well
below the mixing lines. During the winter, the values fell both above and below the
mixing line (Fig. 7a,b,c), which indicated non-conservative mixing (please see discussion
below).

3.4 Spatial and Seasonal Trends in N Loads

Our comparisons of box model net exchange estimates with simulation output
provided by the Chesapeake Bay Program Eutrophication Model (“Bay Model”) revealed
similar TN loads between our results and the Bay Model in the winter, spring, and fall,
with the largest differences in the models evident in the summer months at the boundary
location where tidal fresh transitions to oligohaline conditions and at the mouth of the
estuary (Table S3 and Figures 8 and 9). Even so, these differences are smaller than a
factor of 2 for winter and spring and for most of the summer and fall, despite the
assumption of complete mixing in our box model, a good agreement considering the
simplification of hydrodynamics inherent to a box modeling approach when compared to
the highly constrained CH3D hydrodynamic modeling platform (Cerco et al., 2010). The
Potomac estuary is well mixed along two thirds of its length, and this likely contributes to
our success in applying a single layer box model to this system. The box model also
permitted estimates of TN loads at smaller spatial scales than the three boundaries
available from the Chesapeake Bay Program, which could enable a better interpretation
of where Blue Plains effluent was subject to transformations in the oligohaline portion of
the estuary (Fig. 8). The caveat here is that box-modeled summer loads should be
interpreted with caution because they show the greatest differences from the CH3D
model.
Results of the box model indicated that the net load (kg/day) of TN, NO$_3^-$, and $\delta^{15}$N-NO$_3^-$ decreased down-estuary during each season (Fig. 10a-c, p < 0.05 for winter and spring and p < 0.1 for summer and fall). N loads were highest along the estuary during spring and winter (Fig. 10), and there was a greater decline in TN loads on average from box 1 to box 6 during winter and spring (a loss of ~27,000 ± 15,000 and 50,000 ± 52,000 kg/day, respectively) (Table 1) compared to summer and fall (a loss of ~7,000 ± 8,000 and 15,000 ± 13,000 kg/day, respectively). However, the summer and fall months showed a greater percent decline in TN (75 ± 75% and 112 ± 95%, respectively) compared to winter and spring (54 ± 40 and 36 ± 43%, respectively). The relatively high errors are primarily from the larger uncertainty found in the last box, at the mouth of the estuary, due to the larger size of this box and greater uncertainty in fluxes at the mouth of the estuary; the uncertainties are much smaller further up-estuary (See Fig. 10a). NO$_3^-$ and $\delta^{15}$N-NO$_3^-$ follow the same seasonal patterns as TN. Also, winter, along with summer and fall, showed a greater percent decline in NO$_3^-$ and NO$_3^-$ isotope loads compared to spring (Table 1).

Using an estimated N burial rate of $7.09 \times 10^6$ kg/yr (which is an average of burial rate estimates for the upper and lower Potomac Estuary) from Boynton et al. (1995), it was calculated that, on an mean annual basis, burial accounts for about 77% of the loss in TN. Denitrification was then calculated, by difference, to account for the remaining 23% loss in TN load. Using a different independent method, based on the average annual estimated denitrification rate ($2.8 \times 10^6$ kg/yr) from the upper and lower Potomac (Boynton et al., 1995), and the box model results, it is estimated that denitrification
accounts for about 27% of the TN removal. Consequently denitrification is estimated to account for 23 to 27% of the loss in TN load along the Potomac Estuary.

The percent contribution of TN inputs from the Blue Plains wastewater treatment to the main stem of the Chesapeake Bay ranged from 8 to 47% (Table 1). The contribution was significantly lower during the winter and spring (10 ± 13 and 8 ± 1%, respectively) compared to summer and fall (38 ± 3 and 47 ± 13%, respectively, Table 1), when TN fluxes from all sources are relatively low. The percent contribution of Blue Plains wastewater TN inputs, which are exported to the Chesapeake Bay ranged from <4 to 71%, and they were highest in the spring (71 ± 20%, Table 1). There were also N inputs to the Potomac river-estuarine continuum from the Chesapeake Bay during each season, except spring, due to higher flows (Table 1 & 2) because flow in spring was too high to allow the inputs from the Bay that occurred in the other seasons. NO$_3^-$ and δ$^{15}$N-NO$_3^-$ follow the same seasonal patterns as TN, showing the greatest percentage of inputs from Blue Plains exported during the spring.

4 Discussion

While coastal urbanization can have a major impact on water quality in receiving waters, the results of this study suggest that estuaries also show a large capacity to transform or bury anthropogenic N. In particular, our results suggest that 30-96% of inputs of N from the Washington D.C. Blue Plains wastewater treatment plant were removed via burial or denitrification along the Potomac river-estuarine continuum, depending on the season (Table 1). Recent work shows that urban watersheds and river
networks can also be “transformers” of nitrogen across similar broad spatial scales, which
impacts downstream coastal water quality (Kaushal et al., 2014a). Here, we show that
the urban river-estuarine continuum also acts as a transformer and can have large impacts
on the sources, amounts, and forms of nitrogen transported to the Chesapeake Bay. Our
results showed that N transformation varied across seasons and hydrologic conditions
with important implications for anticipating changes in sources and transport of coastal
nitrogen pollution in response to future climate change. This is particularly significant,
given long-term increases in warming water temperatures of major rivers and increased
frequency and magnitude of droughts and floods in this region and elsewhere (e.g.
Kaushal et al., 2010a; Kaushal et al., 2014b).

4.1 Spatial and Temporal Trends in N Concentrations and Loads

The decrease in DIN concentrations with distance down-estuary is largely from
denitrification, assimilation, and burial, as indicated by the inverse relationship between
NO\textsubscript{3}\textsuperscript{-} concentrations and DOC and TON concentrations, the NO\textsubscript{3}\textsuperscript{-} isotope data, and N
mass balance data discussed below. Dilution from tidal marine waters plays a minor role
in the decrease in DIN and the incoming tidal waters may even contribute to DIN as
suggested by the decrease in DIN slope after 130 km down estuary (Boynton et al.,
1995), depending on the season. The installation of tertiary wastewater treatment
technology at Blue Plains in the year 2000 showed a significant drop in DIN
concentrations within 20-30 km of Blue Plains. However, the DIN concentrations below
30 km down-estuary were approximately the same based on an annual average, before
and after the year 2000. One explanation is that the dissolved wastewater N is
completely assimilated into particulate organic matter (supported by the inverse NO$_3^-$ vs. TON or DOC relationships (Fig.s 3a and 4) or removed by denitrification (as suggested by the isotope data discussed below) within the first 10 km down-estuary, and thus the majority of DIN below 30 km is from other inputs than the Blue Plains wastewater treatment plant. For example, there are 14 other smaller wastewater treatment plants along the Potomac River Estuary, which contribute a total of about 270 mgd (almost as much as the amount Blue Plains contributes). Also, our isotope mixing model data (discussed more below) suggests nitrification (likely of upriver manure or ammonia fertilizer inputs) and fertilizer are important sources further down-estuary; and 42% of the land-use along the Potomac Estuary is agriculture (Karrh et al., 2007b). A second explanation could be related to a change in N:P ratio with distance down-estuary. Specifically, there was a rise in estuarine salinity around 30 to 50 km down-estuary and a coinciding increase in dissolved PO$_4^{3-}$ concentration (typical of the estuarine salinity gradient) (Jordan et al., 2008). When the N:P ratio fell below the Redfield Ratio of 16:1, the estuary could shift from P limitation to N limitation (Fisher et al., 1999). The potential shift from P to N limitation occurred 40-50 km down-estuary, around the estuarine turbidity maximum, which is associated with higher estuarine bacterial productivity (Crump and Baross, 1996), and may be driving DIN removal further down-estuary.

Mass balance indicates that TN and NO$_3^-$ loads decreased down-estuary each season (despite inputs from the 14 other wastewater treatment plants down-estuary). On an annual average, it was estimated that approximately 23-27% of the loss in TN could be attributed to denitrification, while 73-77% was lost through burial into the estuarine
This is supported by the NO$_3^-$ isotope data indicating that there was likely denitrification (an assimilation) of NO$_3^-$, particularly within 6 km down-estuary from the Blue Plains wastewater treatment plant (discussed further below). Over seasonal time scales, there was a greater percent decline in TN loading during summer and fall, likely due to warmer temperatures and increased biological transformation (attributable to high rates of phytoplankton uptake, detrital deposition, and remineralization for subsequent recycling) (Eyre and Ferguson, 2005; Gillooly et al., 2001; Harris and Brush, 2012; Nowicki, 1994), which suggested that the urban river-estuarine continuum may be more efficient at removing TN during the summer and fall. Compared to summer and fall, winter also had a relatively high percent decline in NO$_3^-$ loads possibly driven by the higher concentrations typically found in winter months, which could result in quicker assimilation through first order reaction rate kinetics (Betlach and Tiedje, 1981). Since there was no evidence for denitrification during the winter, burial could also be a mechanism for the relative high decline in winter months, which is typical of higher flows (Boynton et al., 1995; Milliman et al., 1985; Sanford et al., 2001). However, more work is necessary to evaluate the fate of nitrate using ecosystem process level measurements.

The higher total exports of TN and NO$_3^-$ to Chesapeake Bay during the winter and spring are due to greater N inputs from the upper and lower watershed and/or greater flow rates. The proportion of N exports attributed to Blue Plains wastewater treatment plant were the highest in the spring, likely due to lower water residence times (Table 2), resulting in less time for biological uptake, removal, or burial of N. The greater decline in N loads during the spring, however, may be attributed to multiple factors, such as
greater N loads being imported from the upper estuary and higher concentrations, compared to summer and fall (Table 1) and thus driving greater losses (from burial and denitrification) due to first order reaction rate kinetics (Betlach and Tiedje, 1981) similar to winter (described above), stratification that is characteristic of higher flows (Boesch et al., 2001), and increased burial rates due to greater sediment loads during higher flows (Milliman et al., 1985; Sanford et al., 2001). As mentioned previously, more work is necessary regarding linking ecosystem processes and microbial dynamics with the fate of nitrate in the estuary. Nonetheless, the decline in TN and NO$_3^-$ loads down-estuary each season provide strong evidence for the transformation and retention of N along estuaries.

4.2 Spatial Trends in NO$_3^-$ Sources Indicate Denitrification and Assimilation of NO$_3^-$ Initially Dominates and then Nitrification Dominates Further Down-Estuary

The Potomac River estuary was a transformer of wastewater N inputs from the Washington D.C. metropolitan area to its confluence with Chesapeake Bay. The values for $\delta^{15}$N-NO$_3^-$ above the wastewater treatment plant were relatively high, suggesting upriver sources may primarily be from animal waste (Burns et al., 2009; Kaushal et al., 2011; Kendall et al., 2007). This is consistent with a previous study, which found that 43% of N inputs to the upper Potomac River are from manure (Jaworski et al., 1992). Effluent inputs from the Blue Plains wastewater treatment plant significantly increased the $\delta^{15}$N-NO$_3^-$ values even further, yet this NO$_3^-$ signal from wastewater disappeared after 20-30 km down-estuary. The increase in $\delta^{15}$N-NO$_3^-$ and $\delta^{18}$O-NO$_3^-$ values within the first 1 to 6 km down-estuary suggest denitrification or assimilation of nitrate, due to the
lighter $\delta^{14}$N-NO$_3^-$ and $\delta^{16}$O-NO$_3^-$ isotopes being preferentially denitrified or assimilated and leaving behind the heavier nitrate isotopes (Granger et al., 2008; Granger et al., 2004; Kendall et al., 2007) (see further discussion below). But the gradual decline in both $\delta^{15}$N-NO$_3^-$ and $\delta^{18}$O-NO$_3^-$ values from 6 km to 160 km down-estuary suggests nitrification dominates this portion of the estuary because the process of nitrification, which converts ammonia to nitrate results in lighter nitrate isotopes being generated through fractionation (Kendall et al., 2007; Vavilin, 2014) (see further discussion below). However, the decline in $\delta^{15}$N-NO$_3^-$ and $\delta^{18}$O-NO$_3^-$ loads corresponding with the decline in overall NO$_3^-$ loads down-estuary also suggests that the heavy nitrate isotopes are being removed as well as the light isotopes. The disappearance of $\delta^{15}$N-NO$_3^-$ and $\delta^{18}$O-NO$_3^-$ down-estuary where NO$_3^-$ concentrations are very low (~0.01 mg/l) may indicate that assimilation or even denitrification is occurring on the remaining heavy $\delta^{15}$N-NO$_3^-$ or $\delta^{18}$O-NO$_3^-$ after the lighter $\delta^{14}$N-NO$_3^-$ or $\delta^{16}$O-NO$_3^-$ is all used up (Fogel and Cifuentes, 1993; Vavilin et al., 2014; Waser et al., 1998a; Waser et al., 1998b).

Seasonal differences in the longitudinal trends for $\delta^{15}$N-NO$_3^-$ and $\delta^{18}$O-NO$_3^-$ suggest differences in biological transformations of nitrate due to differences in water temperature, hydrology, and/or N inputs. The $\delta^{15}$N-NO$_3^-$ values from effluent inputs were likely higher in warmer months due to higher denitrification rates in the wastewater treatment plant associated with warmer water temperatures (Dawson and Murphy, 1972; Pfenning and McMahon, 1997), resulting in elevated $\delta^{15}$N-NO$_3^-$ values produced by isotopic fractionation (Kendall et al., 2007; Mariotti et al., 1981). An increase in $\delta^{15}$N-NO$_3^-$ between 2 and 6 km down-estuary during summer and fall (Fig. 5b) further suggested increased denitrification or biological uptake due to warmer water.
temperatures and fractionation (Eyre and Ferguson, 2005; Gillooly et al., 2001; Harris and Brush, 2012; Nowicki, 1994). The significant drop in δ\(^{15}\)N-NO\(_3^-\) beyond 10 km down-estuary during summer and fall may have been due to mixing with other N sources and increased nitrification (Wankel et al., 2006) (see further discussion below). During the spring, there was also a significant decline in δ\(^{15}\)N-NO\(_3^-\) between 10 and 160 km down-estuary, but this was likely attributed to dilution and nitrification, based on the conservative mixing results discussed below. The lack of a significant change during the winter, may be due to shorter residence times (Table 2) and cooler temperatures, contributing to lower biological transformation rates. Further down-estuary, near the mouth of the estuary, the increase in δ\(^{18}\)O-NO\(_3^-\) in winter and spring might indicate denitrification in the estuary but in spring nitrate seems conservative based on the salinity mixing plots. The decline in δ\(^{18}\)O-NO\(_3^-\) down-estuary in summer and fall suggest that processes other than denitrification in the estuary are controlling the δ\(^{18}\)O-NO\(_3^-\), such as nitrification.

4.3 Isotope and Salinity Mixing Models Suggest Seasonal Patterns in N Transformation Influenced by Temperature and Residence Time

Seasonally, the ~2:1 relationship between δ\(^{15}\)N-NO\(_3^-\) and δ\(^{18}\)O-NO\(_3^-\) during spring, summer and fall, may indicate denitrification or assimilation, but the salinity mixing plots discussed below suggests no denitrification in the spring. The fact that the δ\(^{15}\)N:δ\(^{18}\)O ratio is between 1 and 2 for summer and fall may suggest assimilation plays a role, which is supported by previous studies which found a 1:1 relationship for assimilation in the marine environment (Granger et al., 2004; Karsh et al., 2012; Karsh et
al., 2014). However, other previous studies suggest that a $\delta^{15}N:\delta^{18}O$ ratio between 1 and 2 can also be cause by denitrifying bacteria (Granger et al., 2008; Lehmann et al., 2003).

Additionally, the divergence from the 2:1 ratio further down-estuary samples may indicate mixing between two or more NO$_3^-$ sources, such as between atmospheric, marine, or nitrification (Kaushal et al., 2011; Wankel et al., 2006). Due to water column dissolved oxygen levels averaging over 4 mg/L (data from Chesapeake Bay program, not shown), assimilation likely dominates NO$_3^-$ removal in the water column, while denitrification likely dominates nitrate removal from the sediment, which supported by previous work (Cornwell et al., 2014; Kemp et al., 1990).

Denitrification is likely a sink for NO$_3^-$ during the summer and fall based on the increases in $\delta^{15}N$-NO$_3^-$ and $\delta^{18}O$-NO$_3^-$ within 6 km down-estuary and due to warmer water temperatures, while there is no evidence for denitrification in the winter due to reduced biological activities typical in cooler winter temperatures (Eyre and Ferguson, 2005; Gillooly et al., 2001; Harris and Brush, 2012; Nowicki, 1994). Nevertheless, nitrate removal was significant in all seasons, including winter suggesting other mechanisms, as indicated by the salinity based mixing lines.

Plots of salinity vs. NO$_3^-$, $\delta^{15}N$-NO$_3^-$, and $\delta^{18}O$-NO$_3^-$ were used to provide evidence for conservative mixing, uptake, production, or contributions from other NO$_3^-$ sources. NO$_3^-$ concentrations fell below the mixing lines during the summer, fall, and winter, suggesting non-conservative mixing behavior due to the presence of a NO$_3^-$ sink, such as assimilation or denitrification (Wankel et al., 2006). During the spring NO$_3^-$ concentrations fell on the mixing line, however, suggesting that there were no important sources or sinks. This may be due to higher flows and shorter residence times in the
spring (Table 2), which can result in less biological transformations of NO$_3^-$

In the salinity vs. $\delta^{15}$N-NO$_3^-$ and $\delta^{18}$O-NO$_3^-$ plots, when the isotope values fell below the mixing lines, this suggested the contribution of NO$_3^-$ from sources with lower $\delta^{15}$N-NO$_3^-$ and $\delta^{18}$O-NO$_3^-$, such as fertilizer inputs or nitrification, which produces nitrate with lower $\delta^{15}$N-NO$_3^-$ and $\delta^{18}$O-NO$_3^-$ values through fractionation (Kaushal et al., 2011; Kendall et al., 2007). An increase in nitrification down-estuary is likely attributed to the conversion of remineralized N to nitrate or from down-estuary inputs of wastewater ammonia that is converted to nitrate (Middelburg and Nieuwenhuize, 2001). During the spring, $\delta^{18}$O-NO$_3^-$, isotope values again fell mostly on the mixing line, which may indicate the Potomac River Estuary is acting more like a transporter instead of a transformer (e.g. Kaushal and Belt, 2012), transporting NO$_3^-$ without there being any significant sinks of NO$_3^-$ or mixing with additional sources, likely due to lower residence times (Table 2) in the spring. However, the fact that during the spring the $\delta^{15}$N-NO$_3^-$ values were slightly below the mixing line indicates there may have been an increased amount of nitrate inputs from the watershed through runoff carrying nitrate derived from nitrification.

During the winter, $\delta^{15}$N-NO$_3^-$ values also fell above the mixing line for some samples, which suggested the contribution of heavy $\delta^{15}$N-NO$_3^-$ from an additional down-estuary source (there are 14 other wastewater treatment plants in the lower Potomac watershed). This was likely not the case during the summer and fall when other sources and sinks may dominate due to greater biological activities (Eyre and Ferguson, 2005; Gillooly et al., 2001; Harris and Brush, 2012; Nowicki, 1994) or during the spring when flows are higher the there is more conservative behavior. Even though only surface water salinity, nutrient, and isotope values were used in these mixing line plots, when bottom water
nutrient and isotope data was averaged with the surface water values, the mixing lines plots and results did not change (data not shown).

5 Conclusion

By coupling isotope tracking techniques and a mass balance over broader spatial and temporal scales, we found that an urban river-estuarine continuum in the Chesapeake Bay, and likely similar estuaries globally can transform anthropogenic inputs of N over relatively short spatial scales. Only a small fraction of N inputs from a major wastewater treatment plant were exported out of the estuary. However, processing of N by estuaries can vary considerably across seasons and hydrologic extremes, with greater exports during periods of higher flows and cooler temperatures, and greater transformations and retention during longer hydrologic residence times and warmer temperatures. In particular, this study supports previous work, showing that non-point sources of N were more dominate during winter and spring when runoff from the watershed and estuarine flows were higher compared to summer and fall when the point-sources were more dominant, due to lower flows. These differences suggest N processing in urban estuaries would differ from those in non-urban estuaries. Also, the potential for long-term and widespread increase in water temperatures and frequency and magnitude of droughts and floods through climate change (Kaushal et al., 2010a; Kaushal et al., 2014b; Kaushal et al., 2010b), will likely influence the sources and transformation of nitrogen to the Chesapeake Bay and estuaries globally. Consequently, future efforts to manage nutrient exports along estuaries would benefit from better understanding the interactive effects of land use and climate variability on the sources, amounts, and transformations of N.
exported to coastal waters and targeting critical times for more intensive wastewater treatment.

</table>

TN = Total Nitrogen. NA – indicates there was only one month with data for that season and thus no S.E. value.

*Blue Plains is a wastewater treatment plant.

Data is based on discharge and box model results for the period from April 2010 to March 2011.
Figures

Figure 1. Map showing the Potomac River sampling stations (black diamond) and the location of the Blue Plains Wastewater Treatment plant (WWTP, black X) just south of Washington D.C., within the Chesapeake Bay watershed. The larger figure shows the location of monthly extensive synoptic surveys sites and the smaller figure on upper left shows the locations of the shorter intensive synoptic surveys. The larger figure also shows the location for the historical Maryland DNR surface water sampling sites.

Figure 2. Plot of the Potomac Estuary depth with distance down-estuary showing the location of the 6 boxes used in the box model calculations.

Figure 3. Longitudinal patterns in Potomac River Estuary: (a) mean annual dissolved inorganic nitrogen (DIN) and total organic nitrogen (TON) spanning 1997 to 2005, (b) mean seasonal DIN before year 2000 (1994 to 1999), and post 2000 (2001 to 2012), and (c) mean (1994 to 2012) seasonal molar N:P ratio (DIN/PO₄³⁻), with salinity averaged from all seasons (1984 to 2008). Note: errors bars are provided, but S.E. is relatively small compared to concentrations. This data was obtained from the Maryland DNR and the Chesapeake Bay Program Data Hub.

Figure 4. Comparison of NO₃⁻ vs. dissolved organic carbon (DOC). N and C data was obtained from the Maryland DNR and the Chesapeake Bay Program Data Hub for this study period.

Figure 5. Trends in (a) δ¹⁵N-NO₃⁻, (b) δ¹⁸O-NO₃⁻, and (c) percent contribution of nitrate from wastewater, the atmospheric, and nitrification, based on isotope mixing model, with distance down-estuary from wastewater treatment plant input. Error bars are standard errors of the mean. N = 1 for winter, N = 3 for spring and fall, and N = 2 for summer.

Figure 6. (a) Plot of δ¹⁵N-NO₃⁻ vs. δ¹⁸O-NO₃⁻ of nitrate from effluent water samples and Potomac River Estuary samples, showing samples from different locations along the estuary; the grey arrow indicates the 2:1 relationship characteristic for denitrification; and (b) Same plot as (a), but seasonally and without the effluent or wastewater outfall values. Not included in these plots is the box indicating the region where atmospheric nitrate samples generally lie, from -10 to +15 for δ¹⁵N-NO₃⁻ and from 60 to 100 for δ¹⁸O-NO₃⁻.

Figure 7. Comparison of salinity vs. (a) NO₃⁻, (b) δ¹⁵N-NO₃⁻ and (c) δ¹⁸O-NO₃⁻. Mixing lines connect the mean NO₃⁻ concentration or isotope values at the lowest and highest salinity values. Error bars are standard errors of the mean. For panel (a), N = 3 for all seasons, for panels (b) and (c), N = 1 for winter, N = 3 for spring and fall, and N = 2 for summer. Mixing line equations for NO₃⁻ concentrations and isotopes were obtained from Middelburg and Nieuwenhuize (2001). NO₃⁻ data was obtained from the Maryland DNR and the Chesapeake Bay Program Data Hub, covering spring 2010 to spring 2011, the same dates as the NO₃⁻ isotope data.
Figure 8. Comparing the TN fluxes along the Potomac River Estuary estimated from the Box Model used in this study and from the results from the Chesapeake Bay nutrient model.

Figure 9. Correlation between the fluxes estimated from the Box Model used in this study and the Chesapeake Bay nutrient model.

Figure 10. Seasonal Box Model results showing how (a) TN, (b) NO$_3^-$, and (c) $\delta^{15}$N-NO$_3^-$ loads vary down-estuary. Error bars are standard errors of the mean. For panels (a) and (b), N = 3 for all seasons. For panel (c), N = 1 for winter, N = 3 for spring and fall, and N = 2 for summer. TN and NO$_3^-$ data was obtained from the Maryland DNR and the Chesapeake Bay Program Data Hub.

Figure 9.

![Graph showing the relationship between Bay Model Flux and Box Model Flux. The graph includes data points for Winter, Spring, Summer, and Fall seasons, along with a one-to-one line.]
Figure 10.

(a) Nitrogen Load (kg day\(^{-1}\)) vs. Distance Down-Estuary (km) for Spring 2010, Summer 2010, Fall 2010, Winter 2011, and Spring 2011. The graphs show a decrease in load as distance increases.

(b) Nitrate Load (kg day\(^{-1}\)) vs. Distance Down-Estuary (km) for Spring 2010, Summer 2010, Fall 2010, Winter 2011, and Spring 2011. Similar trends are observed as in (a), with a decrease in load as distance increases.

(c) Dinitrogen Load (kg day\(^{-1}\)) vs. Distance Down-Estuary (km) for Spring 2010, Summer 2010, Fall 2010, Winter 2011, and Spring 2011. The patterns are consistent with those in (a) and (b), showing a reduction in load with increasing distance.
