General comments:

Authors sufficiently improved the text and figures. However authors do not provide all the material which they refer to in the text.

Specific comments:

Authors provided enough information on the known ways of Yedoma deposition so the problematic saline layer could somehow fit in the Polygenetic concept. We do not wish to go into terminological debate, however, based on this saline layer case authors could have stressed that it differs from the Yedoma Ice Complex, which is syngenetic permafrost. The saline layer on the other hand could still be Yedoma, but not the Ice Complex. However, some ambiguity about this layer has left in view of pollen data (as shown below).

P10 L28-29 – The youngest date from the ice-wedge is not necessarily contamination. We recommend authors to leave some note on the contamination process in the text or think of the latter explanation, otherwise all the dates from the borehole could have been somehow contaminated.

We completed the sentence to:

*The youngest age can be considered as contamination during the drilling process,* due to input of younger material from below.

P12 L19-21 – We did not ask about any unavailable data in our first review. Rather we wonder why the dates from the ice wedge could not be shown by authors. They are widely referred to in the text and should be shown.

We included and presented all available data from the ice wedge in the BK-8 core (radiocarbon dating in tab. 2 and Figure 13, stable isotope data, EC and pH data in Figure 11, 12, and SOM 1). More data do not exist.

P13 L21 – as Konishchev shows in the cited work, the deformations of deposits enclosing ice wedges are not only typical for Yedoma IC but also for other syngenetic ice wedge growth in the soils within some range of mechanical properties. We do not want readers to think of the curved ice layers in contact with ice wedges to be the specific feature of Yedoma IC.

We changed the sentence to be more precise here:

*Due to processes connected with ice-wedge growth, the contact zone is bent upwards. This is a characteristic phenomenon for syngenetic permafrost* ([Konishchev, 2002](#)) *such as Yedoma IC*

P15 L21 – Redeposition of sediments in thaw bulbs is usually reflected by the younger dates compared to the background dates seen on the same level. In this case the dates of the contact zone and saline layer and in-between are older. Given that authors talk about redeposition in segment six as opposed to segment 5 we disagree that ‘segment 6 is a subsequent part of segment 5’ (P10 L4-5).

Thank you for pointing this out. It was a mistake. We changed the sentence accordingly:

*The sixth segment (16.25-18.9 m bs; 17.75.-15.1 m asl) is a part of segment five visible only in the hydrochemical data …*
The accumulation was faster than in the exposures as shown by dating. Could it be a refrozen thaw slump? Redeposition of pollen remains an open question, especially when authors selectively cite Zimmerman’s work for the borehole, but do not show the pollen data from the same aged Yedoma disclosed by exposures. We encourage authors to provide full information on the problematic layer with the subsequent analysis.

*We think the accumulations were in a similar magnitude (Buo-02: 47-29.8 ka, Buo-04: 46 to >55 ka, BK-8: 48.2-57.4 including the standard deviations), but the exposures are something younger than the YIC in the core. Deposition in a thaw slump can be excluded during the late Pleistocene stadial or interstadial climate periods.*

Concerning the redeposition of tree pollen remains in the saline layer (unit 6), those old pollen are often observed in layers where the pollen concentration is low.

*Unfortunately there are no pollen data from the exposure sites Buo-02 and Buo-04.*

Technical comments:

P3 L14 – mistake in ‘therein’

*We changed I accordingly*

P5 L5-6 – ‘and is presented here...’ and the dates after – either correct the missing link or restructure the sentence

*We changed the sentence accordingly to:*

The temperature record for almost three years (May 11, 2012 – April 27, 2015) was read out in late April 2015.

P10 L4 – dash missing in height asl

*We changed it accordingly.*

P10 L6 – incorrect punctuation

*We changed it accordingly.*

P10 L9 – check the 156% of fine sand

*We changed it to ... fine sand (5-15.8%).*

P12 L4 – incorrect punctuation

*We tried to change it accordingly.*

P15 L31-32 – repeat of ‘the study site’

*We changed it accordingly*
SOM1 – please specify what is shown in the table mean+SE or SD and number of samples. Does Buo-02 and Buo-04 represent Yedoma? Column TOC/TN lacks ‘n=’. Please exclude the samples from segment 6 from the values for segment 5, as You pointed out in the text that it is ‘a subsequent part’.

Thank you to point this out. We change the caption accordingly:

SOM 1. Mean values and, standard deviation (±), and sample numbers (n) of the characteristic sediment parameters. Buo-02 and Buo-04 comprise the YIC sequences of the two coastal exposures described in the text.

SOM2 – the pictures are hardly seen

We think that picture quality this will be better in the final version, when the figures are added as higher resolution tiff-format images.
Yedoma Ice Complex of the Buor Khaya Peninsula (southern Laptev Sea)

Abstract. The composition of perennially frozen deposits holds information on the paleo-environment during and following deposition. In this study, we investigate late Pleistocene permafrost at the western coast of the Buor Khaya Peninsula in the south-central Laptev Sea (Siberia); namely prominent eastern Siberian Yedoma Ice Complex (IC). Two Yedoma IC exposures and one drill core were studied for cryolithological (i.e. ice and sediment features), geochemical, and geochronological parameters. Borehole temperatures were measured for three years to capture the current thermal state of permafrost. The studied sequences were composed of ice-oversaturated silts and fine-grained sands with considerable amounts of organic matter (0.2 to 24 wt%). Syngenetic ice wedges intersect the frozen deposits. The deposition of the Yedoma IC, as revealed by radiocarbon dates of sedimentary organic matter, took place between 54.1 and 30.1 kyr BP. Continued Yedoma IC deposition until about 14.7 kyr BP is shown by dates from organic matter preserved in ice-wedge ice. For the lowermost and oldest Yedoma IC part, infrared-stimulated luminescence dates on feldspar show deposition ages between 51.1 ± 4.9 and 44.2 ± 3.6 kyr BP. End-member modelling was applied to grain-size-distribution data to determined sedimentation processes during Yedoma IC formation. Three to five robust end-members were detected within Yedoma IC deposits, which we interpret as different modes of primary and reworked unconfined alluvial slope and fan deposition as well as of localized eolian and fluvial sediment, which is overprinted by in-situ frost weathering. The cryolithological inventory of the Yedoma IC preserved on the Buor Khaya Peninsula is closely related to the results of other IC studies, for example, to the west on the Bykovsky Peninsula, where formation time (mainly during the late Pleistocene MIS 3 interstadial) and formation conditions were similar. Local freezing conditions on Buor Khaya, however, differed, and created solute-enriched (salty) and isotopically-light pore water pointing to a small talik layer and thaw-bulb freezing after deposition. Due to intense coastal erosion, the biogeochemical signature of the studied Yedoma IC represents the terrestrial end-member, and is closely related to organic matter currently being deposited in the marine realm of the Laptev Sea shelf.
1 Introduction

In recent years, considerable research on Quaternary permafrost has focused on a prominent feature of late Pleistocene deposit that is named in stratigraphic terms as Yedoma Ice Complex (IC) after Tumskoy (2012) and Schirrmieister et al. (2013). The Yedoma IC formed in non-glaciated Beringia between about 60 and 12 kyr BP (Marine Isotope Stages (MIS) 4 to 2), including stadial and interstadial stages of the late Pleistocene, although the ages of preserved deposits vary from site to site (Schirrmieister et al., 2011b). Yedoma IC formed in polygonal tundra environments with syngenetic ice-wedge growth. Ice wedges originate from repeated frost cracking of frozen ground in winter and subsequent crack filling by snowmelt water in spring and its re-freezing in the ground. The presence of huge syngenetic ice wedges (up to decameters tall and meters wide) is recognized as characteristic for Yedoma IC, while the depositional processes and sediment sources are still under debate (e.g. Murton et al., 2015). Different depositional regimes are assumed to produce polymodal grain-size distributions, which are commonly found in Yedoma IC (Schirrmieister et al., 2011b). But similar landscape and relief characteristics (poorly-drained flat accumulation plains with polygonal patterned ground), cold-arid climate conditions, periglacial processes such as cryoturbation, frost cracking, syngenetic freezing, and short-path transport of mineral material control Yedoma IC formation (Sher, 1997).

The modern periglacial surface exposes Yedoma IC remnants in Alaskan and East Siberian lowlands next to widely-distributed thermokarst basins (alasses). They were formed after Lateglacial and Holocene warming had eroded up to 70% of the original IC distribution by thawing in an area of more than 1,000,000 km² (Strauss et al., 2013). On the Buor Khaya Peninsula, 85% of the land surface is affected by Lateglacial/Holocene to modern thermokarst (Morgenstern et al., under review).

Numerous case studies have applied multi-proxy approaches at several sites in north-eastern Siberia including the stratotype outcrop for Yedoma IC at Duvanny Yar, which is exposed at the Kolyma River bank (e.g. Gubin and Zanina, 2013, Murton et al., 2015, 2014, Strauss et al., 2012). Poorly-sorted silts and fine-grained sands compose Yedoma IC deposits, which are ice-rich with segregation ice contents between 40 and 60 wt% (Schirrmieister et al., 2011b), and are intersected by ice wedges, which constitute between 31 and 63 vol% of the Yedoma IC (Ulrich et al., 2014). The total ice content of Yedoma IC reaches up to 80 vol%. Lens-like (lenticular) or net-like (reticulated) intrasedimentary ice structures (cryostructures) alternating with horizontal ice bands indicate ice segregation near the permafrost table and syngenetic freezing shortly after deposition. Pronounced ice wedge shoulders indicate the stepwise transformation of seasonally-unfrozen into perennially-frozen deposits due to varying thaw (active) layer depths during formation of syngenetic permafrost.

Yedoma IC is rich in well-preserved floral and faunal fossils, and represents late Quaternary Beringian tundra-steppe environments. Paleontological proxies such as testate amoebae (Bobrov et al., 2004, Müller et al., 2009), pollen (Andreev et al., 2011), plant macrofossils (Kienast et al., 2005), ostracods (Wetterich et al., 2005), and insect fossils and bones of the mammoth fauna (Sher et al., 2005, Wetterich et al., 2008) give insights into past ecosystem and climate conditions, mainly for the summer season. Winter climate during IC formation is commonly deduced from ice-wedge stable water isotope signatures (e.g. Meyer et al., 2002a, 2002b, Vasil’chuk et al., 2001, Vasil’chuk, 2013) that differentiate at least interstadial and stadial stages of the last glacial period (Wetterich et al., 2011b, 2014). The combination of summer and winter proxies sheds light on seasonal trends of past climate and their roles in environmental dynamics.

Eroding Yedoma IC deposits are considered as a major source of terrigenous organic carbon transfer into the Arctic Ocean (Vonk et al., 2012, Winterfeld et al., 2015, Bröder et al., 2016) and represent the terrestrial end-
member of organic matter (OM) on the East Siberian Arctic Shelf (Bischoff et al., 2016). Buried cryosols of Yedoma IC enriched in OM are striking and contribute to a mean total organic carbon (TOC) content of 3 wt% in Yedoma IC (Strauss et al., 2013) that mainly varies between 1 and 5 wt% (Schirrmeister et al., 2011a). Using TC-values Shmelev et al. (2017) estimated 0.6 to 2.1 % TC of carbon storage in permafrost of North-East Yakutia. The fossil OM of Yedoma IC is the subject of ongoing research to estimate the permafrost-locked carbon pool (Hugelius et al., 2014) and its potential feedback to recent climate warming (Schneider von Deimling et al., 2015). The baseline TOC estimates are of further use to study OM quality (Strauss et al., 2015, Stapel et al., 2016) and potential availability for microbial turnover of thawing carbon pools to greenhouse gas emissions in a warming Arctic (Knoblauch et al., 2013). Yedoma IC is considered to be an important pool of OM and potential source of carbon, nitrogen, and nutrient release under current warming (Zimov et al., 2006).

Therefore, analysis of OM preserved in Yedoma IC can improve quantification and prediction of permafrost feedbacks to climate warming.

The cryolithology of several Yedoma IC sites in the Laptev Sea region is summarized in Schirrmeister et al. (2011b) and Tumskoy (2012). But studies of Yedoma IC in north-eastern Siberia started already several decades earlier (e.g. Tomirdiaro (1980), Kaplna (1981), Gubin and Zanina (2013, 2014) and quotations therein), Yedoma IC with very similar characteristics to north-eastern Siberian sites is reported from the Alaskan Itkillik River in the Arctic foothills (Kanevskiy et al., 2011). Studies of East Beringian Yedoma IC were undertaken in permafrost tunnels near Fairbanks (Hamilton et al., 1988, Shur et al., 2004, Bray et al., 2006, Kanevskiy et al., 2008, Schirrmeister et al., 2016). IC of MIS 4 age is well-documented in central Yukon through the presence of the Sheep Creek-K tephra (ca. 80 kyr old; Froese et al., 2009). Further presence of IC deposits is known from the Klondike area (Sanborn et al., 2006).

This study summarizes cryolithological (i.e. ice and sediment features), geochemical, and geochronological data of three Yedoma IC sequences from the Buor Khaya Peninsula in the southern Laptev Sea (Figure 1). We aim to fill a spatial gap in Yedoma IC research in western Beringia between the intensively-studied western and central Laptev Sea regions (including the Lena Delta) to the west (e.g. Schirrmeister et al. 2008, Schirrmeister et al. 2002, Wetterich et al. 2008) and the Dmitry Laptev Strait and the New Siberian Archipelago to the east (Andreev et al. 2009).

By capturing the internal variation of Yedoma IC characteristics, the study deduces stratigraphy and correlates the Buor Khaya Yedoma IC records on a regional scale for Beringia. Since cryolithological properties of Yedoma IC vary from site to site and only about 20 Arctic and Subarctic sites have been studied in detail so far, any new record provides important data for Beringian paleoenvironmental research. Yedoma IC formation processes have been under discussion for decades and each new sedimentary record gives insights into source material, transport, and deposition processes of this unique stratum, which represents a valuable archive and is a main focus in arctic permafrost and paleoenvironmental research.

2 Study site

The Buor Khaya Peninsula is part of the Yana-Indigirka coastal lowlands and is located at the south-central Laptev Sea coast (Figure 1). The vegetation of the Buor Khaya Peninsula is mostly erect dwarf-shrub tundra, with, in places, tussock-sedge and moss tundra (CAVM, 2003). The northernmost part of the peninsula is
covered by sedge, moss, and dwarf-shrub wetlands. In total 77 vascular plant species were recorded during fieldwork in 2010 (Yakshina, 2011).

The subarctic climate is continental, with low precipitation, long harsh winters, and short cold summers. The mean annual air temperature at the closest meteorological station (WMO station 218240, Tiksi, 1981 to 2010) is –12.8 °C (mean temperature of the warmest month, $T_{\text{July}}$: 8.7°C, mean temperature of the coldest month, $T_{\text{January}}$: -32.5°C), and mean annual precipitation amounts 321.5 mm.

The region is underlain by continuous permafrost with ground temperatures of less than -11 °C (Drozdov et al., 2005) which extends down to 450–650 m (Romanovskii et al., 2004). The Yedoma IC of Buor Khaya Peninsula represents the southernmost extent of near-coastal Yedoma IC in a neotectonically-active location south of the Gakkel Ridge landfall.

The Yana-Indigirka coastal lowlands are part of the late Pleistocene accumulation plains of western Beringia. Lateglacial and Holocene warming triggered thermokarst and thermo-erosion, which both have significantly reworked the upper permafrost and shaped the modern surface morphology. Yedoma IC remnants cover 15 % of the area, which consists mainly of coalesced thermokarst basins (alases) and are often occupied by shallow lakes.

Yedoma hills reach up to 37 m above sea level (asl), and thermokarst basins reach 9 to 14 m asl (Günther et al., 2013b).

3 Materials and methods

3.1 Fieldwork

The fieldwork on two Yedoma exposures on the western coast of Buor Khaya Peninsula (Buo-02, N 71.384°, E 132.084°; Buo-04, N 71.600°, E 132.227°) was carried out between August 3rd and 19th, 2010 (Wetterich et al., 2011a). Sediment profiles, partly exposed on thermokarst mounds in thaw slumps, were dug by spades and subsequently cleaned with hoes. The sediments and cryolithological structures were surveyed, described (according to French and Shur. 2011 and Katasonov, 1975), photographed, and sketched. The correlation of the sampling position in neighbouring sub-profiles was done by height estimation using measuring tape. The upper edges of the profiles were measured by tacheometer measurements (Zeiss ELTA C30) to obtain heights asl and to relate sub-profiles. Frozen deposits were sampled using hammers and small axes and packed in plastic bags. Supernatant melt water from segregated ice was separated for isotopic analyses. For selected samples without supernatant water the pore water was sampled using a syringe with vacuum and a microfiltration membrane (0.2 µm pore size, Rhizon Core Solution Sampler, Eijkelkamp). In addition, ice wedges were sampled using ice screws. The absolute ice content was determined in the field as the ratio of ice weight and the weight of frozen sediment. Frozen samples were taken in aluminium boxes, weighed, dried, and weighed again. Volume of frozen sample was determined through the volume of water displacement. We used a vacuum pump and blind measurements of the sample bags. Assuming a water density of 1, the volume of displaced water corresponds to the volume of the sample, which was used for bulk density calculations (Strauss et al., 2013).

Drilling at site BK-8 took place at a distance of about 100 m from the cliff edge on top of a 34.2 m (asl) high Yedoma hill (N 71.4203°, E 132.111°) using a Russian KMB drill rig between April 24th and 27th, 2012 (Günther et al., 2013a). KMB core diameters were 127, 108, 89, and 73 mm. Drilling proceeded in a dry rotary mode without fluids and casing. Core recovery began at the ground surface and continued down to a borehole depth of 18.9 m below surface (bs). An ice wedge was encountered and collected between 3.2 m bs and 8.5 m bs.
The core was described by colour, OM inclusions, and visible sediment and ice structures. Frozen samples were packed and stored frozen in styrofoam boxes.

Ground temperature was measured in the borehole using a 40 m GeoPrecision thermistor string with fifteen PT1000 sensors, installed shortly after drilling. The sensors were calibrated in a purified water (electrical conductivity (EC) < 1 µS/cm) ice bath prior to installation. Sensor output measured in the ice bath was applied as an offset to measured temperatures (1-point calibration). Accuracy of the PT1000 thermistors is better than ±0.1 °C. The temperature record for almost three years (May 11, 2012 – April 27, 2015) was read out in late April 2015, and is presented here (May 11, 2012–April 27, 2015).

3.2 Laboratory work

Sediment samples were freeze-dried, homogenized, and split into sub-samples for further analyses. The volume and weight of frozen and freeze-dried sub-samples were determined for analysis of bulk and dry density and total volumetric moisture content (ice and water). Grain-size analyses were carried out using an LS 200 laser particle analyzer (Beckman-Coulter) after removing OM with hydrogen peroxide (3%). The used grain-size classification is according to Reineck and Singh (1980) and Wentworth (1922). Total carbon (TC) and total nitrogen (TN) contents were measured with a VARIO-EL-III Element Analyzer, while TOC content was measured with the VARIO MAX C. Total sulfur (TS) was measured with a carbon-sulfur determinator (Eltra CS 200). Using the TOC and TN values, the TOC/TN ratio (C/N) was calculated to deduce the degree of OM decomposition. For TOC and stable organic carbon isotope ($\delta^{13}C$) analyses, samples were decalcified for 3 h at 95°C by adding a surplus of 1.3 N HCl. Total inorganic carbon (TIC) content was calculated by subtracting TOC from TC. The $\delta^{13}C$ of TOC was measured with a Finnigan DELTA S mass spectrometer and is expressed in delta per mil notation (δ‰) relative to the Vienna Pee Dee Belemnite (VPDB) standard with an uncertainty of 0.15 ‰. The variations in $\delta^{13}C$ are indicative of changes in the local vegetation and the decomposition degree of OM (Hoefs, 1997). Mass-specific magnetic susceptibility (MS) indicating the content of magnetic and magnetisable minerals was measured using Bartington MS2 instruments equipped with the MS2B sensor type. The data are expressed in SI units (Le Système International d'Unités, $10^{-8}$ m$^3$ kg$^{-1}$).

An end-member modeling analysis (EMMA) was used to determined characteristic grain-size subpopulations that compose the modal grain-size distributions at each site. A robust EMMA was run using the EMMAgeo R-package version 0.9.4. EMMAgeo is based on an algorithm developed by Dietze et al. (2012) that relies on principles of factor analyses and includes different transformation steps to determine a few interpretable grain-size subpopulations (loadings, i.e. contribution of grain-size classes to each end-member). Robust end-members (rEM) are defined as grain-size subpopulations that appear independent of model parametrization (related to a priori unknown numbers of end-members and weight transformation limits, Dietze et al., 2014). Mean rEM loadings and a weight transformation limit of zero were used to calculate mean scores (i.e. relative contribution of an end-member to each sample and their scaled variances) and to model the dataset. Then, goodness-of-fit parameters could be calculated (mean total, class and sample-wise explained variances, i.e. $r^2$ of original vs. modelled data * 100, Dietze et al., 2012).

Radiocarbon dating was performed on plant macro remains by accelerator mass spectrometry (AMS) at the Poznan Radiocarbon Laboratory, Poland (1.5 SDH-Pelletron Model "Compact Carbon AMS") for ten samples of the Buor Khaya exposure profiles (Buo-02 and Buo-04), and at the CologneAMS laboratory, Germany (6 MV Tandetron) for 14 samples of the Buor Khaya drill core (BK-8). Samples were prepared using standard methods.
including acid-base-acid extraction with 1% HCl and 1% NaOH. Extraction times with HCl and NaOH were reduced if the plant fragments were small and fragile to avoid sample destruction or loss. The clean and dry samples were combusted and the CO$_2$ was converted into graphite (Rethemeyer et al., 2013). Conventional radiocarbon ages were calculated following the conventions defined by Stuiver and Polach (1977). Samples were corrected for carbon contributions from exogenous sources using size-matched, radiocarbon-free material (coal), which was processed alike the samples. Samples close to the limit of the radiocarbon method were blank corrected only (a) if the $^{14}$C concentration (fraction modern - Fm) of the sample was larger than those of the corresponding process blank, and (b) if twice the error of the sample's Fm value was smaller than the sample Fm (Stuiver and Polach, 1977). Otherwise a minimum age is reported. The limiting age is calculated as \(-8033 \times \ln(2\sigma)&\) because the 6 MV AMS at Cologne produces lower blank values (due to its higher energy) compared to the Poznan laboratory. Conventional radiocarbon ages are reported in year before present (yr BP). Ages were calibrated using the Calib 7.0.2 software and the IntCal13 calibration curve (Reimer et al., 2013, used in conjunction with Stuiver and Reimer, 1993).

Three frozen segments of the drill core were separated for luminescence dating in order to determine sediment deposition ages (e.g. Aitken 1998). Luminescence dating was applied because the method allows dating of material beyond the limits of radiocarbon dating or evaluating results, when the radiocarbon method reaches the non-finite range of ages. The segments were taken from the lowermost part of the BK-8 drill core (with sample IDs referring to the sample depth in m bs, BK-8_12.95-12.8, BK-8_16.55-16.25 m bs, and BK-8_18.90-18.70). Under subdued light, the outer 2 cm layer of material was removed during controlled thawing to retrieve the inner core part that was not exposed to light during drilling and core preparation. The outer material was used for ice/water content measurements and high-purity Germanium (HPGe), low-level gamma spectrometry of the sediment’s radionuclide content. The inner core part was processed for quartz and feldspar. The lack of pure extractable quartz and coarse-grain material (>100 µm) required focusing on feldspar investigations. Target grain-size fractions were 20-40 µm, 40-63 µm, 63-100 µm, and 90-160 µm, but yields varied largely between samples with generally higher quantities of smaller grains. After the removal of carbonates (10% HCl) and organics (30% H$_2$O$_2$) feldspar was separated from quartz using feldspar-flotation (0.2% HF, pH 2.4-2.7, dodecylamine). Subsequently, density separation was performed to enrich K-feldspars with densities of 2.53-2.58 g/cm$^3$. Although not mandatory, 40 min etching with 10% HF was included for the coarser grains, while for grain-size fractions smaller than 100 µm, etching times were reduced by 5 min per size fraction to remove only the outer 10 µm layer of individual grains.

Preparation of aliquots was done on aluminium discs of 4 mm, 2 mm, and 1 mm diameter, depending on the trade-off between small amounts of material and luminescence signal intensities. The infra-red stimulated luminescence (IRSL) of feldspars was measured using the TL/OSL DA-20 Reader (Bøtter-Jensen et al., 2003), equipped with a $^{90}$Sr beta irradiation source (4.95 Gy/min). Signal stimulation was performed at 870 nm with IR diodes (125 °C for 100 s). The feldspar luminescence emission was collected through a 410 nm optical interference filter to cut off scattered light from stimulation and was detected with a photomultiplier tube (Krbetschek et al., 1997). The measurement sequence followed the single-aliquot regenerative-dose (SAR) protocol according to Murray and Wintle (2000), including tests of dose recycling, recuperation, and correction for sensitivity changes. Appropriate measurement conditions were evaluated and adjusted based on preheat tests and dose-recovery tests (Murray and Wintle, 2003). Processing of measured data and statistical analyses were performed using Analyst v4.31.7 software (Duller, 2015) and the ‘Luminescence’ R package for statistical
computing version 0.6.4. (Kreutzer et al., 2012). The small data sets restricted age-model statistics to measures of central tendency. Therefore, the central age model (CAM) was used for paleodose and IRSL age calculation (Galbraith et al., 1999).

The element (cation) content of ground ice was analysed by inductively coupled plasma-optical emission spectrometry (ICP-OES, Perkin-Elmer Optima 3000 XL), while the anion content was determined by ion chromatography (IC, Dionex DX-320). Hydrogen carbonate concentrations were measured by titration with 0.01 M HCl using an automatic titrator (Metrohm 794 Basic Titrino). Pore-water EC and pH were measured using a WTW MultiLab 540 multi-parameter device equipped with a TetraConTM 325 cell referenced to 20 °C and a pH Sentix 43-1 electrode. The dissolved organic carbon (DOC) concentration in the sediment pore water was measured as non-purgeable organic carbon via catalytic combustion at 680 °C using a Shimadzu TOC-VPCH instrument on samples treated with 20 μl of 30 % supra-pure HCl. Stable isotopes of hydrogen (δD) and oxygen (δ18O) were analyzed on equilibrated samples using a Finnigan MAT Delta-S mass spectrometer following Meyer et al. (2000). Values are reported as per mille difference from the Vienna Standard Mean Ocean Water (VSMOW). Standard deviations were better than 0.5‰ for δD and 0.1‰ for δ18O. The deuterium excess d (Dansgaard, 1964) reflecting isotopic fractionation or exchange processes was calculated by d=δD-8δ18O.

4 Results

4.1 Ground temperature

Ground temperatures measured at 4-hour intervals for almost three years, from May 11, 2012 to April 27, 2015, ranged between -32 and 7 °C, with a mean of around -10 °C (Figure 2). The mean active-layer depth measured from borehole temperatures was less than 0.8 m. The 3-year mean temperature vs. depth profile was relatively flat, with values below the active layer of -10.6 ±0.2 °C. The seasonal temperature amplitude decreased with depth to around 0.1 °C at the bottom of the borehole at 18.5 m bs. According to the data of Romanovsky et al. (2010) our measured temperature is in line with the regional temperatures for Yedoma IC.

4.2 Cryolithology, sedimentology and soil properties

4.2.1 Buo-02

Two composite profiles of Yedoma IC sections (Buo-02 and Buo-04) were studied in 2010 at coastal outcrops on the western shore of Buor Khaya Peninsula (Strauss and Schirrmeister, 2011). The Buo-02 profile extended approximately 10 m from the cliff edge down to a thermo-terrace where deeper-lying permafrost deposits were buried by talus material (Figure 3). Several 2-3 m wide and 5-7 m deep exposed ice wedges were present at a ca. 150 m wide thaw slump. The top of the Yedoma hill was marked with a trigonometric point (30.5 m asl) approximately 100 m away.

The composite Buo-02 profile started at 23 m asl and has four overlapping sub-profiles (A to D; Figure 3). Summary of the characteristic sediment parameters are given in SOM 1. The active layer of Buo-02 was 0.7 m thick and was composed of brownish sand including recent roots. The lowermost part of the active layer at 22.7 to 22.3 m asl consisted of grey and silty sand with several larger plant fragments. Below the permafrost table, from 22.3 to 21.8 m asl, the cryostructure of sub-profile A was horizontally banded (< 1 cm thick bands) and composed of densely-layered ice lenses (SOM 2). Fine ice lenses and vertical veins were observed between the ice bands. The sediment was brownish-grey fine-sandy silt, with sporadic iron oxide patches. At 21 m asl larger
organic patches occurred giving evidence for a cryoturbated paleosol. The uppermost part of sub-profile B was marked by concentric organic-rich patches and plant detritus indicating another paleocryosol horizon. Around these organic patches the sediment was composed of grey-brown silts and fine-sandy silt containing vertical filament roots. The cryostructure was banded, especially visible at 19.5 m asl (SOM 2). In the lower part, lens-like to structureless cryostructures were found. Here at 18 m asl, a paleocryosol with tongues of light-brown material occurred. Sub-profile C was composed of grey to brownish silty fine sand. The uppermost sample was ice-saturated with ice veins up to 10 mm thick. At the underlying parts down to 16.1 m asl, the cryostructures were coarse-to-fine lens-like (SOM 2). In sub-profile D, a remarkable heterogeneity of sediment composition was observed. In the upper part at 18.5 m asl the sediment was composed of greyish silt with brown patches and larger plant fragments. From 17.5 to 17 m asl, a peat layer and peat inclusions appeared, along with vertical and diagonal ice veins. Below the peat layer, the sediment consisted of brownish silty sand with several plant fragments. The cryostructure was micro-lens-like with some ice veins (SOM 2).

The measured absolute ice contents varied between 20 and 90 wt% (Figure 4); ice oversaturation was connected to organic-rich paleocryosol horizons. The grain-size distributions were dominated by fine (18-32%), medium (5-22%), and coarse (15-31%) silt with a clay component (7-14%), and fine (8-30%), medium (5-30%), and small coarse (0.1-1.4%) sand fractions. The mean grain size varied between 26.6 and 69.9 µm (Figure 4). Five robust grain-size end-members (rEM1 to 5) that explain 80.6% of the total grain-size variability in the Buo-02 profile had main modes in the clay to very-fine silt (4.7 µm, rEM1), medium to coarse silt (30 µm, rEM2), coarse silt to very-fine sand (58 µm, rEM3), very-fine sand (111 µm, rEM4), and fine sand (177 µm, rEM5) (Table 1). The profile was dominated by medium to coarse silt (rEM2) and very-fine sand (rEM4) explaining 43 and 38% of the variability, respectively. rEM1, 3, and 5 explained the remaining 19% of variability.

Bulk density (BD) values varied around 1 g/cm³; however, the lowest values of 0.1 g/cm³ were associated with the paleocryosol horizons described above. Mass specific MS value range between 13.7 and 24.5 SI except for two samples of the paleocryosol horizon in sub-profile D (42 and 68 SI). The biogeochemical records of the Buo-02 sequence (Figure 4) varied strongly, with TOC values between 0.3 and 24 wt%, TIC values between 0.4 and 1.8 wt%, TOC/TN ratios of 4.1 to 22.7, and δ¹³C values between -29 and -24.7‰. The TS values were low, between 0.02 and 0.05 wt%.

**4.2.2 Buo-04**

The second composite profile Buo-04 was a 15 m long sequence, which was surveyed downwards starting in front of a steep wall at the cliff edge, crossing the thermo-terrace, and ending at a large thermokarst mound at beach level (Figure 5). Sub-profiles from two thermokarst mounds overlapped. The uppermost sub-profile A (18.5 to 13.6 m asl) was exposed at a steep wall between two longitudinal cut-ice wedges. A summary of the characteristic sediment parameters is given in SOM 1. The uppermost sample was taken from the active layer in the zone of modern vegetation and roots. The frozen deposits consisted of greyish-brown silty fine sand with a lens-like cryostructure and with horizontal ice bands in several parts. The sediments and the ice bands bent on both sides towards the ice wedges. The nearby studied syngenetic ice wedge was diagonally cut by the exposure wall (10 m apparent width). Here, 21 ice-wedge samples were taken at 0.5 m intervals (SOM 3). The light-grey ice wedge contained gas bubbles and several mm-wide vertical sediment stripes. Sub-profile B (10.0 to 7.6 m asl) consisted of greyish-brown silty fine-grained sand. The cryostructure was layered with ice bands < 2 mm thick. Between the ice bands, horizontally-oriented ice lenses occurred (SOM 3). Coarse plant and wood
fragments were visible at 9 m asl. The lowermost thermokarst mound (sub-profile C) was sampled in three places (SOM 3). The uppermost part of sub-profile C between 9 and 7 m asl was characterized by greyish-brown silty fine-grained sand and the occurrence of plant detritus, much root material, and smaller plant stems. At 8.5 m asl coarse lens-like ice bands occurred. These bands appeared at 5 cm intervals and ice lenses (< 1 mm thick and 0.5 to 1 cm long) in the sediment interlayers were reticular oriented. At 8 m asl, a matrix of greyish-brown silty fine sand contained a peaty cryoturbated paleosol. Plant detritus was layered at 7 m asl. The sediment in the middle part of sub-profile C between 6.8 and 5.5 m asl became sandier with depth. The peaty- and horizontally-bedded layers continued. In addition, coarse plant and wood fragments were found at 6.5 to 6.0 m asl. At 6.8 m asl, the deposits were ice super-saturated and the cryostructure was composed of coarse ice lenses surrounding plant fragments. Ice bands less than 0.5 to 4 mm thickness occurred. The lowest part of sub-profile C (5 to 4 m asl) was sandier and drier. Here a yellowish light-grey matrix with iron oxide spots and broken ice lenses as well as horizontal ice fissures indicated a disturbance of the deposits (SOM 3).

The absolute ice contents of the Buo-04 sequence varied between 22 and 59 wt%. The grain-size distribution was again dominated by fine (10-25%), medium (7-25%), and coarse (26-41%) silt fractions and a clay component (6-14%). The sand contents were low (4-10 wt%) in the uppermost sub-profile A (18.5 to 13.6 m asl) but similar to the Buo-02 sequence (21-43 wt%) in the B and C sub-profiles (9.6 to 4.3 m asl). This was also mirrored in the mean grain-size values between 21.2 and 27.5 µm in sub-profile A and 33.6 and 54.4 µm in sub-profiles B and C. Three rEMs describe 73.7% of the grain-size distributions of the Buo-04 sequence (Table 1). The clay to very-fine silt rEM1 (main mode at 4.7 µm as in Buo-02) accounts only for 9% of the variance in the grain-size data set. The medium silt rEM2 (main mode at 25 µm) explains 43% and the very-fine sandy rEM3 (main mode at 76 µm) accounts for 48% of the explainable grain-size variance.

BD values varied between 0.5 and 1.5 g/cm³ with increasing values in the lowermost part. The MS values were relatively high in sub-profile A (41.1-47.7 SI) except for the lowermost sample at 13.6 m (14.3 SI), which is the lowest value of the entire record. The other parts were characterized by little variation between 20 and 30 SI. The Buo-04 sequence showed TOC values from 0.2 to 4.7 wt%, TIC values from 0.3 to 1.1 wt% (both lower than in Buo-02), TOC/TN ratios from 5.6 to 25.3, and δ¹³C values between -28.8 and -25.4‰. The TS values varied between 0.02 and 0.05 wt%. Higher TOC contents and TOC/TN ratios as well as the lowest δ¹³C values were associated with the occurrence of a paleocryosol horizon around 6 to 8 m asl.

4.2.3 BK-8

According to a detailed cryolithological description (SOM 4 and 5), the BK-8 core was sub-divided in the field into five segments completed by a sixth segment characterized by specific pore-water composition (Figure 7). Characteristic sediment parameters are summarized in SOM 1. The active layer (0-0.35 m bs, 34-33.65 m asl) is the uppermost core segment consisting of brown silty fine-grained sand with plant remains and roots. Segregated ice was characterized by irregular, partly transvers-diagonally and horizontally-arranged micro, fine, and coarse lens-like cryostructures. The second segment (0.35-3.4 m bs, 33.65-30.6 m asl) contained grey-brown silty fine-grained sand, plant remains, and woody fragments (twigs, roots). The cryostructure was coarse irregular lens-like. Sub-vertical ice veins (1-5 mm wide, 10-15 cm long) occurred. Between 3.4 and 8.35 m bs (30.6-25.65 m asl) the core cut an ice wedge of clear colourless ice with gas bubbles <1 mm in diameter and parallel-oriented vertical sediment stripes up to 5 mm thick. The fourth segment (8.35-9.95 m bs, 25.65-24.05 m asl) represented the contact zone between the ice wedge and the sediment, and was composed of grey-brown silty fine-grained
sand and plant remains with a diagonal coarse lens-like cryostructure and several upturned ice bands. The fifth segment (9.95-16.0 m bs, 23.85-18.0 m asl) consisted of horizontally-bedded grey-brown silty fine-grained sand, mostly with only a few plant remains. In several layers, larger (~ 5 mm) woody plant fragments occurred, coated by ice crusts. The cryostructure showed horizontal alternations of fine lens-like reticulated and coarse lens-like reticulated interlayers and cm-thick ice bands. The sixth segment (16.25-18.9 m bs; 17.75-15.1 m asl) is a subsequent part of segment five only visible only in the hydrochemical data and will be described more detailed in chapter 4.4.

The absolute ice contents of the BK-8 core varied between 66 and 84 wt% (Figure 8). The grain-size distribution was relatively uniform, dominated by fine (12-20%), medium (11-24%), and coarse (23-33%) silt and containing clay (9-15%), fine sand (5-15%), medium sand (7-20%), and a small fraction of coarse sand (1-8%) components. The mean grain size varied between 31.2 and 73.6 µm. Four rEM were found and account for 74.1% of the variability in the BK-8 grain-size data (Table 1): a clay rEM1 (main mode at 2.7 µm), a medium silt rEM2 (main mode at 25 µm), a very fine-grained sand rEM3 (main mode at 76 µm), and a fine-grained sand rEM4 (main mode at 213 µm) explained 16, 33, 7, and 44% of the variance in the grain-size data, respectively.

BD values varied between 0.6 and 1.6 g/cm³, without a clear trend along the core, while MS values (12-38 SI) increased with depth. In general, the biogeochemical data are in a similar range as that from the Buo-02 and Buo-04 exposure sequences with TOC contents between 0.8 and 7.4 wt%, TIC contents between 0.2 and 0.5 wt%, TOC/TN ratios of 6.3 to 15.6, and δ¹³C values between -28.8 and -25.4‰. The TS values vary between 0.02 and 0.08 wt%.

4.3 Dating

Radiocarbon dates were obtained from five Buo-02 profile samples between 16 and 22.3 m asl, and ranged between 45.0 ± 2 and 30.1 ± 0.3 kyr BP (Table 2). Five samples (between 6.8 and 17.1 m asl) from the lower-lying Buo-04 profile had mostly non-finite ages and an uppermost sample had an age of 49.0 ± 3 kyr BP. Both profiles showed deposition of the Yedoma IC during interstadial MIS3.

Samples were selected from the BK-8 14 drill core for radiocarbon dating, including four plant fragments and OM samples that were isolated from the ice wedge (Table 2). The five ages from above the ice wedge were between 3.35 and 0.3 mbs (30.65 and 33.7 m asl) covered the Late-glacial period with ages of 11.4 ± 0.05 to 9.7 ± 0.05 kyr BP. The four ages from the ice wedge showed a broad range, between 22.1 ± 0.1 and 5.1 ± 0.05 kyr BP. The youngest age can be considered as contamination during the drilling process, due to input of younger material from below. Five ages obtained from below the ice wedge, between 16.1 and 8.8 m bs (17.9 and 25.2 m asl), ranged between 54.1 ± 3.4 and 50.3 ± 2.1 kyr BP.

The Yedoma IC below the ice wedge was dated by IRSL at three depths: 12.95-12.8 m bs, 16.55-16.2 m bs, and 18.9-18.7 m bs. The dating results for different grain-size fractions are summarised in Table 3. Applying the CAM, the deposition ages of the 12.95-12.8 m bs core interval are 46.1 ± 3.5 kyr, 44.2 ± 3.6 kyr, and 45.4 ± 4.8 kyr as obtained from different available grain size fractions of 63-100 µm, 40-63 µm, and 20-40 µm, respectively. The 16.55-16.2 m bs core interval has an age of 44.2 ± 3.3 kyr (from the 90-160 µm grain-size fraction only). The lowermost IRSL-dated 18.9-18.7 m bs core interval provided grain-size fractions of 90-160 µm, 63-100 µm, and 40-63 µm, yielding ages of 45.6 ± 5.5 kyr, 45.9 ± 3.5, and 51.1 ± 4.9 kyr, respectively.

Only low aliquot numbers were available in sample BK-8; 12.95-12.8 m bs in the 63-100 µm and 20-40 µm
fractions as well as in the 18.9-18.7 m bs 90-160 µm fraction sample. Therefore, the estimated age information from these analyses is of lower probability. However, the overlapping age ranges in both samples where different grain-size fractions were dated show a general agreement of all ages in the samples. The deduced deposition age ranges are 47.8 to 40.6 kyr for BK-8 12.95-12.8 m bs, 47.5 to 40.9 kyr for BK-8 15.55-15.2 m bs, and 56.0 to 42.4 kyr for BK-8 18.9-18.7 m bs.

4.4 Hydrochemistry, stable water isotopes

Stable isotope ratios of Buo-02 pore ice ranged between -27.9 and -19.6‰ for δ¹⁸O and -220.4 and -166.0‰ for δD, and d-excess values between about -14.1 and 15.4 ‰ (Figure 9). The EC varied between 550 and 3500 µS/cm. DOC concentrations lay below 400 mg/l except for three samples with high values up to 1272 mg/l. The pH was slightly basic and generally trended from over 8 near the top of the profile to values below 8 at the bottom.

Stable Buo-04 pore ice isotope ratios showed a trend from lower values (around -32.5‰ for δ¹⁸O and -241.8‰ δD) to higher values (-20.4‰ for δ¹⁸O and -155.9‰ δD) with depth (Figure 10). Variable d-excess values ranged between -3.9 to 22.5‰. EC showed an inverse trend with height, from high values of almost 2400 µS/cm at the upper end of the profile to 200 µS/cm at the bottom. The pH was slightly basic (7.5 to 8.2). DOC values, except for one data point, were below 200 mg/l.

The pore space solution from the BK-8 core showed considerable hydrochemical variability with depth (Figure 11). Stable isotope ratios were highest in the active layer, and were lower and decreased in the Lateglacial to early Holocene cover above the ice wedge. Isotope ratios in the ice wedge were lower (δ¹⁸O -31.2 to -31.9 ‰) than values in the underlying Yedoma IC; the latter exceeded -28.5 ‰ and -215.8 ‰ between 17.5 and 25.6 m asl. At the bottom of the core, however, isotope ratios declined from 17.5 m (δ¹⁸O -28.5 ‰) down to their lowest values at 15.5 m asl (δ¹⁸O -34.6 ‰). This coincided with increasing d-excess values, up to almost 23.6‰. The pore solution EC lay between 100 and 1000 µS/cm (approx.. 70 - 360 mg/l by summing major ion concentrations) in sediment above the ice wedge. The ice wedge was relatively pure, with EC < 100 µS/cm.

Below the ice wedge, the pore-space solution EC ranged from >500 to 4000 µS/cm (approx.. >140 – 1600 mg/l). The ECs in the bottom portion of the core, corresponding to the depths at which lower stable isotope ratios were observed, were high, between 7000 and 14,000 µS/cm (approx. 3600 – 7700 mg/l). DOC concentrations were generally below 400 mg/l, except for most samples between 19 and 23 m asl, some of which had DOC concentrations in excess of 1000 mg/l. The solution pH was between 5 (active layer, around 21 m asl) and 8, but most samples were basic. Solute concentrations followed the EC.

Anion concentrations in the active layer and the Lateglacial to early Holocene cover were dominated by Cl⁻ and SO₄²⁻, the latter particularly at the transition from Lateglacial to early Holocene cover to ice wedge. Measurable NO₃⁻ concentrations were observed only in the uppermost two samples of the active layer. Cation concentrations over the same depths were highest for Na⁺ (7-40 mg/l), Ca²⁺ (6-80 mg/l), with maxima and minima associated with the active layer or the transition to the underlying ice wedge. All solute concentrations in the ice wedge were less than 10 mg/l. Immediately below the ice wedge (below 26 m asl), concentrations of Cl and Na were all high, with variation over 1-2 orders of magnitude with height. Below 18 m asl, concentrations of a number of solutes increased markedly by another order of magnitude: Cl (over 4 g/l), Na (up to 960 mg/l).

Stable isotope ratios are grouped based on source and on their relationship to one another. Samples from BK-8 and the exposures range from -35 to more than -20‰ δ¹⁸O (Figure 12). Within this range, samples grouped
above the Global Meteoric Water Line (GMWL) at low values, near the GMWL and Local Meteoric Water Line
(LMWL) for mid-range values, and below the GMWL for mid-range to higher values. This is reflected in the
relationship between d-excess and $\delta^{18}O$, for example. The lightest samples in BK-8 had positive d-excess and
came from the 16-18 m asl depth range. High d-excess values correspond to the lowest $\delta^{18}O$ values. A decrease
in d-excess (-8.6 ‰), or the lowest d-excess values (-14.1 ‰) were observed in BK-8 at 23-25 m asl and in Buo-
02 at 18 m asl heights, respectively. Samples recovered from ice wedges, whether in the borehole or not, cluster
tightly along the LMWL with lighter values, as expected for this winter precipitation signal. Values from
Lateglacial to early Holocene cover more closely resemble meteoric waters (rain), both in magnitude and in their
ratio to one another.

## Discussion

### 5.1 Chronostratigraphy

The chronostratigraphy of the Buor Khaya Yedoma IC and its overlying Lateglacial to early Holocene cover is
based on 24 radiocarbon dates and three IRSL datings of the lowermost BK-8 core Yedoma IC unit (Figure 13).
The Buo-04 profile and the BK-8 core deposits below the ice wedge exhibit radiocarbon ages between 54.1 ± 3.4
and 49 ± 3 kyr BP as well as non-finite ages in Buo-04. The IRSL ages of the lowermost BK-8 core segments
range between 51.1 ± 4.9 kyr and 44.2 ± 3.6 kyr.

Continued Yedoma IC formation is assumed by sedimentary radiocarbon ages of the Buo-02 profile between
45.0 ± 2 and 30.1± 0.3 kyr BP, and ages from the BK-8 ice wedge between 22.1 ± 0.1 and 14.7 ± 0.06 kyr BP.
The thermokarst onset during the Late glacial period is a commonly observed feature of late Quaternary
permafrost stratigraphies (Kaplina and Lozhkin 1979, Kaplina, 1981, Romanovskii et al., 2000, Wetterich et al.,
2009, Walter Anthony et al., 2014). The radiocarbon ages obtained from OM within the BK-8 ice wedge,
however, confirm that Yedoma IC formation occurred between about 30 and 14 kyr BP; these dates are not
present in the obtained sedimentary records and ages.

Generally, studying permafrost stratigraphies in paleoenvironmental research by sampling coastal exposures in
sub-profiles and drill cores introduces certain considerations that must be accounted for during data
interpretation. The preservation of late Pleistocene ice-rich permafrost depends, not only on predominant climate
dynamics, but also on paleo-relief conditions and the past spatial distribution of accumulation and erosion areas.
To capture the kilometre-scale spatial variability, sampling of coastal exposures advances our understanding of
this variability, or at least provides the chance to relate records of the same age spatially. As shown in Figure 13
the oldest Yedoma IC units with non-finite radiocarbon ages were found at different altitudes, below 15 m asl for
profile Buo-04 and between 16 and 9 m asl for core BK-8; this points to different deposition heights within the
former surface morphology. The Buo-04 and Buo-02 Buor Khaya Yedoma IC profiles, even though they were
sampled at similar altitudes, cover different periods of Yedoma IC deposition; the Buo-04 represents formation
>49 kyr BP, and the Buo-02 represents deposition between about 45 and 30 kyr BP. The exposure accessibility
and technical difficulties encountered in keeping the sampled material frozen during summer field campaigns as
well as the lower sampling resolution, if compared to permafrost drilling in springtime, limit the quality of
exposure data. The drilling approach allows for higher sampling resolution of frozen material and better borehole
instrumentation for e.g. ground temperature measurements. The core material is also limited since it is difficult
to choose a drilling location from the ground surface that gives a representative sample and avoids ice wedges. This study attempts to combine the advantages of both stratigraphic sampling methods.

5.2. Cryostratigraphy and analytical data interpretation

The Buo-02 and Buo-04 profiles (Figures 3 to 6) show no distinct internal stratification that allows cryolithological units to be defined within both sequences. However, paleocryosol horizons at 17 to 18 m asl in Buo-02 and at 6 to 8 m asl in Buo-04 are remarkable in ice content, BD, TOC, C/N, and δ¹³C values of TOC. These horizons are also noteworthy in heavier stable water isotope values and lower d-excess values (Figures 9 and 10). However, the hydrochemical data sets do not indicate relevant lithostratigraphical separations. The increasing and decreasing trends of stable water isotope values and EC values, respectively, will be considered separately.

The BK-8 core is divided into six cryolithological units, according to field observations, core descriptions, and analytical data sets. The active layer (34.0-33.45 m asl) is characterized by the lightest stable water isotope values (-19.3 to -17.1 ‰ for δ¹⁸O, -147.2 to -125.7 ‰ for δD) and the lowest pH values (5.6 to 4.5). The deposits of the Lateglacial-early Holocene cover (33.45-30.85 m asl) have properties similar to those of the overlying active layer. However, the stable water isotope signature is clearly different, with a decreasing shift downwards to the underlying ice wedge (Figure 11). According to pollen data (Zimmermann et al., 2016), the deposits were formed in a shrub-tundra landscape indicating regional climate amelioration during this glacial-interglacial transition period (Andreev et al., 2011). The ice wedge of the BK-8 core (30.8-25.65 m asl) is clearly distinguishable as a separate unit due to its specific structural characteristics and ground-ice composition. The contact zone (25.65-24.05 m asl) between IC deposits and the ice wedge is made obvious by diagonally- and vertically-oriented cryostructures. In addition, there is a clear decrease in TOC, TS, δ¹³C, EC, and d-excess values, while δD and δ¹⁸O increase. It should be remarked that the contact zone is bent upwards due to processes connected with ice-wedge growth, which is a typical characteristic for syngentic permafrost (Konishchev, 2002) such as Yedoma IC (Konishchev, 2002). Below the ice wedge, the horizontally-bedded Yedoma IC unit is cryostratigraphically distinguished only by the horizontally-oriented cryostructures, while sediment and ice characteristics are similar to those in the covering contact zone. Pollen analyses from both segments, the Yedoma contact zone and the regular Yedoma, indicate the presence and partial absence of hydrophytes, respective, reflecting the occurrence of a perennial shallow polygon pond with temporally-fluctuating water level (Zimmermann et al., 2016). Finally, the lowermost saline layer (18-15.1 m asl) was distinguished due to increased EC values of up to 14 mS/cm. In addition, the MS values are higher than those in the overlying Yedoma IC deposits.

5.3. Sediment transport and depositional processes from grain size end-members

According to the end-member analysis (Figure 14) each Yedoma IC sequence is characterized by a specific robust end-member (rEM) signature. However, three typical end-members (rEM1 to rEM3) with similar patterns are modeled in all three records. The fine-silt rEM 1 (main mode at 3-5 µm) was present in most Buo-02 and Buo-04 samples but did not dominate the sections, while in the BK-8 permafrost core, it was present mainly in the Lateglacial-early Holocene cover and in two samples at 21.5 and 20.5 m asl. Hence, this rEM might represent an alluvial, unconfined transport of fine material. The medium-silt rEM2 (main mode at 25-30 µm)
dominated the upper Buo-04 (down to 13.6 m asl) and was rarely found in the lower part of the profile. In BK-8, rEM2 is present in most samples and dominates the lower part. A slight difference appears in Buo-02, where rEM2 is common in three segments separated by dominant coarser end-members. Its broader main mode is shown in Figure 14 A to C, which could point to a secondary transport mechanism involved. For example, after aeolian deposition on the slopes the sediment was relocated towards the site in unconfined alluvial flow (similar to what is described in Dietze et al., 2012). The very fine-sand rEM3 (main mode at 60-80 µm) dominated the sand layers in Buo-02 at 15.5, 17, and 18.5 m asl. The rEM3 also characterizes the sand layers in Buo-04 at 16, 22, 24-25, 31, and 33.5 m asl, and even dominates the entire lower part of this profile (Figure 14 D to F), but appears only sporadically in the BK-8 core sequence. We assume a short-term localized aeolian transport during peak wind intensities to have created these layers (Tsoar and Pye, 1987; Dietze et al., 2014). In Buo-02 two additional end-members (rEM4, rEM5) were separated in the fine-sand fraction with the main modes at 111 and 177 µm, respectively, while in BK-8 rEM4 was calculated in the medium-sand fraction with a main mode at 213 µm. These three specific sandy rEMs might be related to short-term fluvial (confined) transport processes, as they are too coarse for aeolian transport (Tsoar and Pye, 1987). The various grain-size end-members support the hypothesis of polygenetic Yedoma IC origin involving multiple transport and depositional processes, which might be overprinted by in-situ frost weathering.

5.4. Polygenetic origin of Yedoma soils

The Yedoma IC formation comprises primary soil accumulation and cryogenic processes, for instance cryogenic weathering, ice segregation, syngentic ice wedge growth, secondary sediment deformation, and reworking due to cryoturbation. Such processes were supported by the long-lasting severe continental climate conditions of the late Pleistocene. Moreover, the formation of large polygon ice-wedge nets and thick continuous ice-rich permafrost deposits was related to the existence of stable, poorly-drained accumulation plains with low inclination. In contrast to the loess hypotheses of Yedoma IC formation (e.g. Tomirdiaro, 1980, Murton et al., 2015), the proposed cryolithogenetic concept integrates several previous formation concepts and, in particular, takes into account the important role of ground ice in the deposit formation process. Generally, this corresponds to the polygenetic character of Yedoma IC formation. It also includes the potential for several sediment sources, weathering processes, and pathways by which sediments in typical periglacial landscapes can build up the Yedoma IC.

Whereas the EC of pore solutions in Buo-02, Buo-04, and most of BK-8 is less than 3000 µS/cm throughout, pore solutions below 19 m asl exceed 10 mS/cm, which is not typical for Yedoma IC sediments, and require explanation. The pore water geochemistry of permafrost may reflect differences in mineral source material and the mechanical and biochemical weathering of that material, but may also be affected by processes active during deposition or processes that occurred following deposition and freezing. Concentration of solutes can result from phase change (evaporation or sublimation of surface waters, exclusion and migration of solutes from freezing pore solution) (Jouzel and Souchez, 1982) and can lead to secondary effects such as the precipitation of mineral phases from solution.

We suggest that the saline layer at the bottom of BK-8 is the result of Rayleigh fractionation during the re-freezing of a thawed layer from above. There are numerous points to support this interpretation: Firstly, neither the age nor the composition of the BK-8 mineral component show changes correlated with the more concentrated solution, with the possible exception of somewhat higher MS. Secondly, the concomitant increase
in d-excess and decrease in $\delta^{18}O$ and $\delta^D$ for pore water below 16 m bsl (below 18 m asl) suggest Rayleigh fractionation during phase change. The negative correlation between $\delta^D$ and d-excess (with a slope of -0.2) reflects freezing processes rather than meteoric precipitation as a source (Souchez et al., 2000, Lacelle, 2011). Based on the distribution of both over depth, freezing occurred from above in the segment from at least 16 m down to the bottom of the core at 18.4 m depth. Isotope ratios are consistent with Rayleigh fractionation from source water with the isotope ratio in the Yedoma IC above this lowest segment, using the equilibrium coefficients for the fractionation of $\delta^{18}O$ and $\delta^D$ during freezing from Suzuoki and Kimura (1973), so that an exogenous water source is not necessary to explain the change in isotope ratios over depth. Thirdly the increased EC below this depth is consistent with solute concentration due to the removal of solvent by freezing from the pore solution. The pore water composition does not support an exogenous source for the hydrochemistry: means of major dissolved species concentrations (Na⁺, K⁺, Mg²⁺, Ca²⁺, Cl⁻) in sea water, marine brines, normally bedded BK-8 Yedoma, and BK-8 saline layer with higher EC also suggest a non-marine origin for the higher concentration of solutes (Figure 15). Taken together, the isotope concentrations and EC indicate that unidirectional freezing from above of the lower 2.5 meters of BK-8 took place in a medium that was necessarily unfrozen. The presence of high but variable concentrations of solutes in the pore water throughout this layer is generally consistent with concentration effects in slowly freezing soils (Chuvilin, 1999), but the source of the solutes is not clear, since their concentration exceeds what would be available in the Yedoma IC sequence.

We therefore suggest that during the warm and moist summer conditions of the MIS 3 interstadial period (Andreev et al., 2011, Wetterich et al., 2014) a talik horizon more than 2.5 m thick developed and subsequently re-froze making it post-depositional epigenetic permafrost. Such thawing and re-freezing can be observed, for example, in thaw bulbs beneath small water bodies such as polygon ponds (Langer et al., 2011). Our borehole was not deep enough to capture the lower boundary of this post-deposition refreezing process nor to determine how local this phenomenon is.

According to pollen data from Zimmermann et al. (2016), the saline layer segment of the BK-8 core is characterised by increasing wetness (e.g. algae and spores) but also increasing shrub and tree taxa (Pinus, Picea, Betula, and Alnus), which presumably originated from redeposited pre-Quaternary pollen.

Our comprehensive cryolithogenetic concept of polygenetic Yedoma formation (Schirrmeister et al., 2013) combines cryogenic weathering, periglacial material transport and accumulation, and relief shaping under cold-arid climate conditions and considers two general formation processes: (1) primary accumulation in low-centered ice-wedge polygons and (2) syngenetic freezing and ice-wedge growth. Following this concept, the Yedoma IC represents a specific periglacial facies whose formation is controlled by the interaction of climate, landscape, and geological preconditions typical for non-glaciated Arctic and sub-Arctic lowlands and foothills.

### 5.5 Regional context of Yedoma Ice Complex in eastern Siberia

Comparing the records of the Buor Khaya Yedoma IC with the well-studied profiles of the Bykovsky Peninsula (Figure 1; e.g. Schirrmeister et al., 2002, Sher et al., 2005, Grosse et al., 2007) about 100 km west, the study sites, the study site of Mus Khaya on the Yana River about 150 km southeast (Konishchev, 2013) as well as with the coastal exposure from Bol’shoy Lyakhovsky Island (Figure 1; Andreev et al., 2009, Wetterich et al., 2011a, b, 2014) about 350 km northeast of Buor Khaya Peninsula, we come to conclusion that these sections formed during the same period between about 60 and 12 kyr BP (late MIS 4 to MIS 2) that is typical for Yedoma IC
formation (Schirrmeister et al., 2011b). The cryostructures observed at the studied Yedoma IC sequences as well as the major cryolithological parameters are also similar in range and internal variations. In this sense the Buor Khaya Yedoma IC generally belongs to the same late Pleistocene paleoenvironment and was formed under similar paleoclimatological and paleogeographical conditions as Yedoma IC remains around the Laptev Sea.

The ground temperature record (Figure 2) does not show any specific variations due to paleo-warming signals or heat transfer from the Laptev Sea. However, the typical warming of cold permafrost around the Arctic (Romanovsky et al., 2010) and in Siberian Yedoma boreholes at Cape Mamontov Klyk in the western Laptev Sea (Overduin et al., 2008) or at the Mamontovy Khayata site on the Bykovsky Peninsula (Kholodov, 2009) was not observed here.

Summarizing the OM characteristics, the Yedoma IC deposits from the Buor Khaya Peninsula contain 2.04 $\pm 1.27$/-1.05 wt% TOC (median with interquartile ranges). The TOC/TN ratio (to estimate the degree of OM decomposition) ranges between strongly decomposed (4.1) and not decomposed (31.3) states. High OM contents are less decomposed and low OM contents are strongly decomposed ($\ln(Y) = 0.446 \times \ln(X) + 1.94$, $R^2 = 0.82$, n=97, Figure 16). The $\delta^{13}$C OM values vary between -29.0 and -24.7 ‰. According to Meyers (1997), the relationship between atomic TOC/TN ratios and $\delta^{13}$C of TOC reflects the existence of C3 land plants as well as lacustrine algae. Comparing the analyzed DOC pore water concentration of about 10 to 1370 mg/l with the free acetate fraction within the pore water studied by Stapel et al. (2016) of up to 500 mg/l it can be concluded that the DOC is composed of substantial proportions of free acetate.

When considering that the Yedoma IC exposed at the Laptev Sea coasts provides source material for marine deposits and is a terrigenous end-member of organic carbon on the east Siberian shelf, the study of the composition and formation of Yedoma IC is essential to understanding the fate of terrigenous OM across the Laptev Sea as studied by Bröder et al. (2016), whose marine transect began in the Buor Khaya Bay. The $\delta^{13}$C signatures for marine surface sediments are −26.6 to −25.6 ‰ from the Buor Khaya Bay (Bischoff et al., 2016) and −26.5 to −22.2 ‰ for a transect across the Laptev Sea (Bröder et al., 2016). The range of TN values (0.03 to 0.45 wt%) and atomic TOC/TN ratios (21.7 to 68) of Buor Khaya Bay surface sediments presented by Winterfeld et al. (2015) span ranges similar to those of the Buor Khaya Yedoma IC deposits (TN: 0.1 to 0.47 wt%, atomic TOC/TN ratio: 4.8 to 36.5). These OM parameters reflect the fact that important parts of terrestrial OM still remain in marine surface deposits and support studies of source, transport, and fate of OM on the East Siberian Arctic Shelf, starting with the terrigenous end-member, i.e. eroding permafrost coasts.

Conclusions

The studied Yedoma IC permafrost exposed at the western coast of the Buor Khaya Peninsula in the central Laptev Sea accumulated from about 54.1 ± 3.4 kyr BP (IRSL age 51.1 ± 4.9 kyr) until the onset of the Lateglacial to Holocene warming. The timing of IC formation and its cryolithological properties are similar to known Yedoma IC sequences in the Laptev Sea region. Three to five robust end-members (rEMs) represent fine silt, medium silt, and fine sand fractions in grain-size distribution data, which support the concept of multiple transport and depositional processes during IC formation. Post-depositional refreezing processes during the MIS3 interstadial with relatively warm and moist summer conditions created unusually high solute concentrations in pore water. The OM characteristics of the Yedoma IC reflect typical continental tundra-steppe
environments of western Beringia during the late Pleistocene. Eroding Yedoma IC deposits are one of the OM sources in the marine realm of the Laptev Shelf.

Acknowledgments

The study presented here is part of the Helmholtz-Russia Joint Research Group. We gratefully acknowledge the German Federal Ministry of Education and Research (BMBF) for funding this study as part of the joint German-
Russian research project CARBOPERM (03G0836B, 03G0836F). Moreover, we acknowledge the support by the European Research Council (Starting Grant #338335) and the Initiative and Networking Fund of the Helmholtz Association (#ERC-0013). We thank our colleagues who helped during fieldwork in 2014, especially Dmitry Mel'nichenko and colleagues from the Hydrobase Tiksi, and Waldemar Schneider from AWI Potsdam who greatly supported the logistics of this expedition. The analytical work in the AWI laboratories was expertly conducted by Ute Bastian, Dyke Scheidemann, Antje Eulenburg, Hanno Meyer, and Lutz Schönicke. We are grateful to Marcus Richter (TU Dresden) and to Ingrid Stein (TU Bergakademie Freiberg) for IRSL analyses and to Jörg Erzinger, Sabine Schumann (GFZ Potsdam), and Torben Windirsch (University of Potsdam) for TS measurements. Finally, the paper benefited from reviews of Mikhail Kanevskiy (University of Alaska Fairbanks) and one anonymous reviewer by constructive comments and English language correction from Candace O'Connor (Fairbanks Alaska).
