

LETTER TO THE EDITOR

Dear Dr. van der Meer,

Thank you for your comments and for your continued interest in our manuscript. We have incorporated your suggestions which included (1) new figures showing confidence intervals, and (2) a few clarifications of the text. In addition, we have done some minor fixes/updates of the manuscript.

Best regards,

Gustaf Granath and co-authors

RESPONSE TO EDITOR COMMENTS

I find that the s after composition in line 75 (annotated version) feels a bit weird.

RESPONSE: Changed.

In line 245 you use occasions, but perhaps time points is better.

RESPONSE: Changed.

Line 278 you have data from samples from a broad geographical area, I am not sure the current description works, although it is clear what you mean.

RESPONSE: Reformulated.

Line 322, the water film reduces CO₂ transport and therefore results in less than maximum fractionation (or results in reduced fractionation).

RESPONSE: reformulated. "thus maintaining the waterfilm that hampers fractionation." -> "thus maintaining the waterfilm that results in reduced fractionation."

In line 343, enabling increased discrimination against (or increased fractionation).

RESPONSE: "enabling discrimination against" -> "enabling increased discrimination against"

Line 366, fewer precipitation collection stations, or weather stations?

RESPONSE: "fewer collection stations" -> "fewer precipitation collection stations"

Lines 382-384, to the best of my knowledge isotopically heavy water rains out first and with orographic uplift typically precipitation becomes more "depleted" with higher elevation not more "enriched" in ¹⁸O. Could the "amount" effect perhaps also play a role in your dataset?

RESPONSE: The text was referring to the study by Skrzypek et al. (2010) which did not find expected trends with altitude. It is correct that their non-significant result may be caused by variation in the precipitation amount at different elevations that can obscure altitude--d¹⁸O relationships. We have re-written this part.

Environmental and taxonomic controls of carbon and oxygen stable isotope composition in *Sphagnum* across broad climatic and geographic ranges

75 **Abstract.** Rain-fed peatlands are dominated by peat mosses (*Sphagnum* sp.), which for their growth depend on nutrients, water and CO₂ uptake from the atmosphere. As the isotopic composition of carbon (^{12,13}C) and oxygen (^{16,18}O) of these *Sphagnum* mosses are affected by environmental conditions, the *Sphagnum* tissue accumulated in peat constitutes a potential long-term archive that can be used for climate reconstruction. However, there is a lack of adequate understanding of how isotope values are influenced by environmental conditions, which restricts their current use as environmental and

80 palaeoenvironmental indicators. Here we tested (i) to what extent C and O isotopic variation in living tissue of *Sphagnum* is species-specific and associated with local hydrological gradients, climatic gradients (evapotranspiration, temperature, precipitation), and elevation; (ii) if the C isotopic signature can be a proxy for net primary productivity (NPP) of *Sphagnum*; and (iii) to what extent *Sphagnum* tissue δ¹⁸O tracks the δ¹⁸O isotope signature of precipitation. In total, we analysed 337 samples from 93 sites across North America and Eurasia using two important peat-forming *Sphagnum* species (*S.*

85 *magellanicum*, *S. fuscum*) common to the Holarctic realm. There were differences in δ¹³C values between species. For *S.*

magellanicum $\delta^{13}\text{C}$ decreased with increasing height above the water table (HWT, $R^2=17\%$) and was positively correlated to productivity ($R^2=7\%$). Together these two variables explained 46% of the between-site variation in $\delta^{13}\text{C}$ values. For *S. fuscum*, productivity was the only significant predictor of $\delta^{13}\text{C}$ but had low explanatory power (total $R^2=6\%$). For $\delta^{18}\text{O}$ values, approximately 90% of the variation was found between sites. Globally-modelled annual $\delta^{18}\text{O}$ values in precipitation explained 69% of the between-site variation in tissue $\delta^{18}\text{O}$. *S. magellanicum* showed lower $\delta^{18}\text{O}$ enrichment than *S. fuscum* (-0.83‰ lower). Elevation and climatic variables were weak predictors of tissue $\delta^{18}\text{O}$ values after controlling for $\delta^{18}\text{O}$ values of the precipitation. To summarise, our study provides evidence for **(a)** good predictability of tissue $\delta^{18}\text{O}$ values from modelled annual $\delta^{18}\text{O}$ values in precipitation, and **(b)** the possibility to relate tissue $\delta^{13}\text{C}$ values to HWT and NPP, but this appears to be species-dependent. These results suggest that isotope composition can be used at a large scale for climatic reconstructions but that such models should be species-specific.

1 introduction

Peatlands in temperate, boreal and arctic regions form large reservoirs of carbon, which are vulnerable to release under expected changes in global climate and land management (Rydin and Jeglum 2013, Loisel et al. 2014). Because peat decomposes slowly and gradually accumulates, it preserves information on past peatland ecosystem dynamics and responses to allogenic and autogenic forcings. Palaeoenvironmental studies of peat may, therefore, help anticipate future responses of these globally important ecosystems to climate change (Loader et al. 2016). Past climate and local hydrology can be estimated using a variety of biotic and biogeochemical proxies, including the $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values of organic material (e.g. van der Knaap 2011, Royles et al. 2016, Lamentowicz et al. 2015). However, the environmental (e.g. climate) and biotic (e.g. species identity) controls of isotope differentiation in peatland-dwelling plants are still poorly understood and current assumptions regarding these controlling factors are yet to be tested at larger spatial scales.

Sphagnum mosses are the most dominant peat-forming plant group in acidic peatlands. The composition of stable isotopes of carbon and oxygen in their tissues is affected by different environmental conditions, operating through their impact on fractionation processes. When not submerged, carbon isotope signals in bulk tissues or components such as cellulose depend mainly on the concentration and isotopic composition of CO_2 in the chloroplast, which alters isotope discrimination during biochemical fixation of CO_2 (Farquhar et al. 1989, O'Leary 1988). In mosses, the CO_2 concentration in the chloroplast, $[\text{CO}_2]_c$, is determined by temperature, light availability, CO_2 partial pressure and, most importantly, plant water status (Finsinger et al. 2013, van der Knaap et al. 2011, Ménot and Burns 2001, Ménot-Combes et al. 2004, Royles et al. 2014, Skrzypek et al. 2007a, Kaislahti Tillman et al. 2013). When wet, external water films on leaf surfaces impede diffusion and $[\text{CO}_2]_c$ is lowered (Rice and Giles 1996, Rice 2000, Williams and Flanagan 1996); consequently, the proportion of fixed ^{13}C increases due to internal drawdown of the preferred isotope ^{12}C . When submerged, assimilation of respired or methane-derived CO_2 can alter $[\text{CO}_2]$ and also the isotopic composition of C in *Sphagnum* (Raghoebarsing et al. 2005). Even when

not submerged, respiratory carbon can be refixed by *Sphagnum* (Turetsky and Wieder 1999, Limpens et al. 2008). Given that respired CO₂ is isotopically lighter than that in the atmosphere, it may also contribute to variation in tissue isotope values. Despite many detailed studies, there remains uncertainty about how the multiple controls on ¹³C isotope values combine to determine isotopic composition, and how universal the proposed mechanisms are on a global scale. This uncertainty currently restricts the utility of C isotope signals as a palaeoclimatic/palaeoenvironmental indicator in peatlands (Loader et al. 2016).

Oxygen isotope values in moss tissues depend on the isotopic composition of the water sources, enrichment associated with evaporation from the moss surface and biochemical fractionation (Dawson et al. 2002). Once on the plant, ¹⁸O present in water equilibrates with that in atmospheric CO₂ prior to fixation as well as being incorporated directly during hydrolysis reactions, especially during the initial stages of carbon fixation (Gessler et al. 2014, Sternberg et al. 2006). Hence, variation in tissue oxygen isotopes reflect environmental conditions that control source water (rainfall, snowfall, groundwater) as well as fractionation caused by evaporation prior to fixation which is controlled by micrometeorological conditions (mainly temperature, relative humidity and incident energy) (Daley et al. 2010, Moschen et al. 2009, Royles et al. 2013, Kaislahti Tillman et al. 2010). Oxygen isotope composition has, therefore, been used to reconstruct climatic conditions and to infer the dominant water source in peatlands (Aravena and Warner 1992, Ellis and Rochefort 2006, van der Knaap et al. 2011). Ongoing measurements of oxygen isotopes in precipitation across the globe (Bowen 2010, IAEA/WMO 2015) have generated models that predict spatial patterns in oxygen isotope composition of precipitation based on temperature, elevation, atmospheric residence time and circulation patterns (e.g. Bowen 2010). Once isotopic composition of the source water is accounted for, variation in moss tissue isotopic values should be largely determined by fractionation that accompanies evaporation from the surface of plants. How well oxygen isotopes in *Sphagnum* tissues reflect atmospheric water or plant surface water depend on local weather conditions such as precipitation, air temperature and humidity. For example, Bilali et al. (2013) suggest that oxygen isotopes in *Sphagnum* mosses from maritime bogs will track variation in precipitation patterns whereas isotopic values in continental habitats will be more dependent on summer temperature, as temperature and humidity are more variable in those regions. At local scales, oxygen isotope values also vary as a function of temperature and humidity. Aravena and Warner (1992) found differences that correspond with changes in microtopography. Elevated microsites (hummocks) were enriched in ¹⁸O, which they ascribed to higher evaporation compared to that of neighbouring wet depressions (hollows). However, as with ¹³C, there remains uncertainty in how ¹⁸O signatures relate to environmental factors and species identity, and to what extent global ¹⁸O patterns in precipitation dominate over local processes.

Stable isotopes can also serve as indicators of primary productivity (NPP) (Rice and Giles 1996, Williams and Flanagan 1996, Rice 2000). However, few studies have explored these relationships in the field. In a multispecies comparison of peat mosses, Rice (2000) found that plants with higher relative growth rates had lower discrimination against ¹³C and therefore

were more enriched in ^{13}C . This was attributed to the local environment, with fast growing plants of wetter microhabitats having thicker water films that inhibits CO_2 diffusion into the plant, and to species-specific differences in maximum rates of photosynthesis. Both factors would reduce internal $[\text{CO}_2]$ and thereby lower discrimination. In line with this, a warming experiment by Deane-Coe et al. (2015) reported a positive relationship between moss net primary productivity (NPP) and $\delta^{13}\text{C}$ values for tundra mosses (*Dicranum*, *Pleurozium*, *Sphagnum*). Clearly, carbon isotope values show promise as indicators of peat moss contemporary growth, and potentially as an NPP proxy in paleoecological studies. This could be particularly valuable to differentiate productivity and decomposition controls in long-term carbon accumulation studies. To date, we are not aware of attempts to explore the robustness of these relationships across large spatial scales.

160

Together, tissue carbon and oxygen isotope compositions are controlled both by environmental factors at micro- and macro-scales, and by species-specific differences that relate to water balance and carbon dynamics in peat mosses. Paleoecological studies rely on such environment— $\delta^{13}\text{C}$ relationships for environmental reconstructions (Ellis and Rochefort 2006, van der Knaap et al. 2011). The underlying mechanisms are, however, rarely fully explored using known environmental gradients (but see Ménot and Burns 2001 for an example), or only tested across narrow bands of environmental variation, often with sets of correlated environmental factors (Loader et al. 2016). Moreover, interactions with biotic factors such as species identity have received little attention despite the large variations in *Sphagnum* species dominance commonly observed down peat cores (e.g. Ménot and Burns 2001). Here we aim to provide a robust, cross-scale evaluation of how environmental factors and species identity influence the C and O isotope compositions of *Sphagnum* using two common and widely distributed peat-forming species (*S. magellanicum* and *S. fuscum*) that are primarily rain-fed. To achieve this, we performed a unprecedented large sampling campaign across the Holarctic realm.

Specifically, we (i) investigated relationships between C and O isotope values and factors known to influence plant water availability (height above the water table - HWT, temperature, evaporation and precipitation) and CO_2 partial pressure (elevation), and tested if their effects were modified by species identity; (ii) tested the prediction that *Sphagnum* tissue $\delta^{13}\text{C}$ values are associated with NPP; (iii) tested if tissue $\delta^{18}\text{O}$ in rain-fed Sphagna is predicted by the $\delta^{18}\text{O}$ isotope signature in precipitation but modified by negative relationships with precipitation and positive ones with temperature/evaporation. Across these objectives we examined how C and O isotope values varied with scale (within-peatland *versus* between-peatlands) and to what extent HWT and NPP could explain variation within and between peatlands.

180 2 Materials and Methods

2.1 Study species and collection sites

Our study focused on two common peat-forming *Sphagnum* species, *S. fuscum* (Schimp.) H. Klinggr. (circumpolar distribution) and *S. magellanicum* Brid. (cosmopolitan distribution). In general, these species are confined to primarily rain-

fed peatlands (bogs), and described as hummock (*S. fuscum*) and lawn (*S. magellanicum*) species. However, *S.*
185 *magellanicum* is a species with a very broad niche and found in a range of habitats with varying degrees of groundwater
influence (Flatberg 2013). These species are easy to identify but recent research has shown that the dark European morph of
S. fuscum is conspecific to the North American *S. beothuk* (Kyrkjeeide et al. 2015), and *S. magellanicum* has been shown to
consist of two genetically diverged morphotypes (Kyrkjeeide et al. 2016)- that recently were separated at the species level
(Hassel et al. 2018). Unpublished genetic data suggest that samples collected in our study consist of both *S. magellanicum*
190 morphs (approximately 50/50) and possibly one or two samples of *S. beothuk* (Pers. comm. N. Yousefi). Hence, we here
treat our species as aggregates (i.e. species collectiva), *S.fuscum* coll. and *S. magellanicum* coll.

The two species were sampled across the Holarctic region at a total of 93 sites (Figure 1; Supplemental Table S1) at the end
of the growing season. To make comparisons between species and between sites possible, we focused on habitats where both
195 species can be found and have low influence of surrounding groundwater. Thus, we only sampled bogs (including a few poor
fens with ombrotrophic character) and open (no tree canopy) habitats. Sampling was conducted mainly during 2013, but a
few sites were sampled at a similar time of year in 2014. At each site two patches (minimum 10 m apart) for each species
were sampled (except for 11 sites that contained only one patch for one species). At each sampling patch we recorded moss
growth, HWT (height above the water table) and GPS coordinates, and collected a moss sample (78 cm² and 5 cm deep) at
200 the end of the growing season (September to November depending on location and generally coincided with when there was
a risk of the first snowfall to occur). Moss samples were dried (24 hrs at 60-65 °C) within 72 h, or alternatively immediately
frozen and later thawed and dried. The apical part (the capitula, top 1 cm) of the dried plant shoots was used for isotope
analysis, while the stem section was used for bulk density estimation to calculate moss NPP.

2.2 Isotope determination

205 Ten capitula from each patch were selected and finely chopped with a single-edge razor by hand and mixed. Capitula were
chosen as they reflect the most recently fixed organic matter and should relate better to recent growing season conditions. In
Sphagnum, $\delta^{13}\text{C}$ from the capitulum is similar to that of branches within the top 15 cm plants, but is approximately 1-2 ‰
less negative than stems (Loader et al. 2007). For $\delta^{18}\text{O}$, the offset between branches and stems is around 1 ‰ (Moschen et
al. 2009). Standard deviations of repeated samples were 0.6 and 0.7 ‰ for $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$, respectively. Approximately 0.5
210 mg dry sample was packed in tin cups for $\delta^{13}\text{C}$ analyses, and ~0.2 mg in silver cups for $\delta^{18}\text{O}$ analyses. Samples were
analyzed at Union College (Schenectady, NY, USA) using a Thermo Delta Advantage mass spectrometer in continuous flow
mode connected (via a ConFlo IV) to a Costech Elemental Analyzer for $\delta^{13}\text{C}$ analysis or a Thermo TC/EA for $\delta^{18}\text{O}$ analyses.
Isotope values are presented as $1000 \times (R_{\text{sample}}/R_{\text{standard}}-1)$, where R_{sample} and R_{standard} are the ratios of heavy to light isotopes
(e.g., $^{13}\text{C}/^{12}\text{C}$) and are referenced to VPDB and VSMOW for C and O, respectively. Carbon isotope data were corrected
215 using sucrose (IAEA-CH-6, -10.449‰), acetanilide (in house, -37.07‰), and caffeine (IAEA-600, -27.771‰). Oxygen
isotope data were corrected using sucrose (IAEA-CH-6, 36.4‰), cellulose (IAEA-C3, 31.9‰) and caffeine (IAEA-600,

-3.5‰) with values from Hunsinger et al. (2010). Oxygen isotope standardization was further checked with the whole wood standards USGS54 and USGS56. The combined instrument uncertainty for $\delta^{13}\text{C}$ (VPDB) is $< 0.1\text{‰}$ based on the in-house acetanilide standard and $< 0.5\text{‰}$ for $\delta^{18}\text{O}$ (VSMOW) based on the cellulose standard (IAEA-C3).

220

We performed isotope analyses on whole-plant tissue rather than on cellulose extracts. In living *Sphagnum* samples, there is strong linear relationship between the isotopic composition of these two components for both $\delta^{13}\text{C}$ (R^2 values 0.89-0.96; Kaislahti Tillman et al. 2010, Ménot and Burns 2001, Skrzypek et al. 2007b) and for $\delta^{18}\text{O}$ (R^2 values 0.53-0.69; Kaislahti Tillman et al. 2010, Jones et al. 2014). Focussing on whole-plant tissue allowed us to analyze a higher number of samples for
225 this study, allowing larger numbers of sites and more replication.

2.3 Environmental variables

The modelled $\delta^{18}\text{O}$ signal in meteoric water (precipitation) (Bowen and Wilkinson 2002) was obtained from <http://www.waterisotopes.org> as annual and monthly isotope ratio estimates at $10'$ resolution. These global estimates have shown to be highly accurate ($R^2 = 0.76$ for mean annual $\delta^{18}\text{O}$ in precipitation) and are based on absolute latitude and
230 elevation and account for regional effects on atmospheric circulation patterns (for details see Bowen 2010, IAEA/WMO 2015, Bowen 2017). To test which temporal period of $\delta^{18}\text{O}$ values in precipitation showed the highest correlation with tissue $\delta^{18}\text{O}$ values, we calculated annual (Jan-Dec), growing season (May-Oct), winter-spring (Jan-April) mean isotope ratio. We calculated both unweighted means and weighted against precipitation for each month. Monthly precipitation (PRECTOTCORR), land evapotranspiration (EVLAND) and surface air temperature (TLML) for each site and year of
235 sampling (2013 or 2014) were retrieved from the NASA GESDISC data archive, land surface and flux diagnostics products (M2T1NXLND, M2TMNXFLX; resolution longitude 0.667° , latitude 0.5° ; Global Modeling and Assimilation Office 2015ab). Total precipitation and evapotranspiration (ET), and mean temperature, from April to October were used as predictors in the statistical models. As ET can be compensated for by precipitation, we used the ET/P quotient as a predictor for the effect of water loss. A high value (>1) indicates a net loss of water to the atmosphere. Site altitude was retrieved from
240 a global database using the R package *elevatr* (ver 0.1-2, Hollister and Shah 2017).

The distance from the moss surface to the water table (height above the water table, HWT), was measured using water wells (commonly a PVC pipe, 2–5 cm in diameter and slotted or perforated along the sides) with a “plumper” (a cylinder on a string that makes a ‘plump’ sound when it hits the water surface) or a “bubbler” (a narrow tube that makes bubbles when it
245 hits the water surface while the user blows in it). HWT was measured in the spring and in the fall and there was a strong correlation between the [two time points](#) ($r = 0.74$). As growth mainly occurs in late summer/fall in temperate and boreal regions, we used HWT at the the end of the season as the proxy of relative HWT between sites.

2.4 Moss growth

Moss growth (or productivity, NPP) was measured with a modified version of the cranked wire method (see Clymo 1970, Rydin and Jeglum 2013 for details), with bristles from a paint brush spirally attached to a wire. These ‘brush wires’ were inserted in the moss layer with the end of the wire protruding above the surface. Height increment (i.e. vertical growth) was measured over the growing season as the change in distance (to nearest mm) between the moss layer and the top of the wire. A minimum of three wires were inserted within a 1 x 1 m uniform area (same microhabitat, vegetation and general structure). To determine moss bulk density (kg m^{-3}) we dried (24 hrs at 60-65 °C) the top 30 mm of the stems (area 78 cm^2) in our collected core (see Sect. 2.1). Biomass growth on an area basis ($\text{g m}^{-2} \text{year}^{-1}$) was calculated as height increment \times bulk density.

2.5 Statistical analyses

To test and quantify the influence of environmental variables and species identity on isotope composition, we used linear mixed models in R (R core team 2016), employing the R package *lme4* ver 1.1-12 (Bates et al. 2015). Site dependence (i.e. multiple samples from the same site) was accounted for by adding site as a random factor. For tissue $\delta^{13}\text{C}$, we first fitted two separate models to test the independent effects of HWT, NPP and species identity (*S. fuscum* and *S. magellanicum*), and if the HWT or NPP effect varied between species by fitting a species interaction term. To test the explanatory power of environmental variables (ET/P, precipitation, temperature, elevation) we first constructed a base model with HWT and NPP as they were identified as the main predictors in literature. For simplicity we removed negligible interactions from this model. Each environmental variable and their interaction with species was then tested against the base model. For tissue $\delta^{18}\text{O}$, we first explored which temporal period of modelled $\delta^{18}\text{O}_{\text{precip}}$ (annual, growing season, winter-spring) had the highest explanatory power and if the relationship varied between species. The identified best model was then used as base model to separately test each environmental variable (HWT, ET/P, precipitation, temperature) and its interaction with species.

The proportion of variance explained by the predictors was calculated at the site level (Gelman and Hill 2007) or as marginal R^2 (Nakagawa and Schielzeth 2013; R package *piecewiseSEM* ver 1.1-4, Lefcheck 2015). Although our study focused on explained variance by predictors, we also performed statistical tests of predictors and their interactions using type-2 (main effects tested after all the others in the model but without the interaction term) *F*-tests, applying Kenward-Roger adjustments to the degrees of freedom, as implemented in the *car* package (ver. 2.1-3, Fox and Weisberg 2011). Standard model checking was performed (e.g., residual analyses and distribution of random effects), to ensure compliance with model assumptions. Covariances between predictors were small ($r < 0.15$) or moderate ($r = 0.40$ - 0.50 between ET/P, precipitation and temperature) and this multicollinearity had minor impact on model estimates.

3 Results

280 | Data collection from a geographically broad area resulted in large variation of isotope values and explanatory variables (Table S2). Due to uncertainty in height increment measurement we recorded a few negative values resulting in negative NPP. These values were kept in the analyses. Mean and standard deviation (in parenthesis) of height increment (HI, mm) and bulk density (BD, kg m⁻³) were: HI for *S. fuscum* 14.3 (10.1) and *S. magellanicum* 19.5 (14.1), BD for *S. fuscum* 17.8 (9.9) and *S. magellanicum* 10.2 (7.6).

3.1 δ¹³C signal

285 Variation in *Sphagnum* tissue δ¹³C values was marginally greater within sites than between sites (Table 1). HWT predicted the δ¹³C values, but the relationship differed between the two species (Table 2, Figure 2). Although δ¹³C values decreased with increasing HWT for both species, the slope was less steep for *S. fuscum* and this species had slightly higher δ¹³C values overall. In separate models for the two species, HWT for *S. fuscum* had near zero explanatory power, while for *S. magellanicum* HWT explained 33% of the between-site variation, and 17% of the total variance (i.e., marginal R²).

290

Measured δ¹³C values were related to moss productivity (NPP), and δ¹³C values increased by 0.0023‰ (SE: 0.00048) for each mg biomass produced per m². NPP explained 11% of the between-site variation in δ¹³C and 7% of the total variation. HWT and NPP, explained 48% of the between-site variation of δ¹³C in *S. magellanicum*, and 24% of the total variation. Corresponding values for *S. fuscum* were 6% and 7%, respectively. Of the additional environmental variables tested, we
295 found weak evidence that ET/P and temperature were positively correlated with δ¹³C, but only for *S. magellanicum* (Table 2).

3.2 δ¹⁸O signal

Sphagnum tissue δ¹⁸O values varied more between sites than within sites, and at similar magnitude and proportions for both species (Table 1). Tissue δ¹⁸O values were predicted by the spatially explicit estimates of δ¹⁸O values isotope signature in
300 precipitation (Figure 3, Table 3). Annual mean δ¹⁸O_{precip} explained 69% of the variation in δ¹⁸O_{tissue} between sites. This was similar to mean winter-spring (Jan-Apr) δ¹⁸O_{precip} values (75% explained), but higher than growing season (Apr-Sep) δ¹⁸O_{precip} (58%). Using precipitation-weighted δ¹⁸O_{precip} values resulted in lower percentages of explained variance for all three time periods (R²_{site}: annual 52%, Jan-Apr 65%, Apr-Sep 52%). *S. magellanicum* had consistently lower δ¹⁸O values than *S. fuscum* (-0.83‰), but both species had a similar relationship between tissue δ¹⁸O and δ¹⁸O_{precip} (Figure 3, Table 3).

305

Height above the water table (HWT) at the end of the growing season was, on average, 11 cm lower in *S. magellanicum* patches (= wetter habitat) compared to *S. fuscum* (HWT = 33 cm) patches (F_{1,224} = 131.9, P < 0.0001). However, we found only very weak support for the hypothesis that HWT predicts tissue δ¹⁸O values, as HWT explained <1% of the δ¹⁸O

variation (Table 2). There was negligible influence of the additional environmental variables on $\delta^{18}\text{O}$ values (Table 2). ET/P
310 was associated with higher $\delta^{18}\text{O}$ values in *S. magellanicum* and lower in *S. fuscum* (but not different from zero effect), while
increasing temperature was weakly associated with overall lower $\delta^{18}\text{O}$ values.

4 Discussion

4.1 Stable carbon isotope discrimination in *Sphagnum*

Our data were consistent with the hypothesis that moss growing closer to the water table (low HWT) has reduced carbon
315 isotope fractionation, leading to greater fixation of $^{13}\text{CO}_2$ and more ^{13}C enriched tissue (Rice and Giles 1996, Williams and
Flanagan 1996). Given that the water table position was measured in different places at different times and all are one-time
measurements, this result is remarkably robust. For example refixation of ^{12}C enriched substrate-derived CO_2 in living
Sphagna (Turetsky and Weider 1999, Raghoebarsing et al. 2005) can potentially contribute to within-site variation in $\delta^{13}\text{C}$ as
it potentially affects both the ambient concentration of CO_2 as well as its isotopic composition. Interestingly, the strength of
320 the $\delta^{13}\text{C}$ - HWT relationship differed in the two species, with *S. magellanicum* exhibiting a greater reduction in $\delta^{13}\text{C}$ in
response to drier conditions (high HWT) than *S. fuscum*. The weaker effect of HWT on $\delta^{13}\text{C}$ values in *S. fuscum* is likely a
consequence of limited fluctuation in tissue water content as this species is well known to store abundant water within
capillary spaces and resist drying (Rydin 1985), thus maintaining the waterfilm that [hampers results in reduced](#) fractionation.
Loader et al. (2016) reported a similar slope estimate for *S. magellanicum* in a single peatland and several studies have
325 confirmed effects of contrasting microtopography (i.e. hummock—hollow differences) using multi-species comparisons
(Price et al. 1997, Loisel et al. 2009, Markel et al. 2010). As such, our results suggest that species-specific differences in
carbon isotope discrimination in *Sphagnum* are related to water retention capacity and, consequently, become more apparent
under drier conditions. This supports the results of previous, smaller-scale studies (Rice 2000).

330 The influence of species identity on the relationship between $\delta^{13}\text{C}$ values and water table position has important implications
for palaeoenvironmental reconstructions based on $\delta^{13}\text{C}$ values. The relationship between $\delta^{13}\text{C}$ and HWT has been used in
paleoecological reconstructions of surface wetness (e.g., Loisel et al. 2009). In our dataset the strength of the relationship
was weaker than previously reported. For instance, Loader et al. (2016) reported $R^2 = 54\%$ for *S. magellanicum* in a single
site. Given the characteristics of our data (large-scale, circumpolar), the explanatory power ($R^2_{\text{marginal}} = 17\%$) can be
335 considered acceptable and comparable to other proxies such as testate amoebae (16% in Loader et al. 2016; Sullivan and
Booth 2011). Our results imply that isotopic signals of peatland wetness in hummock-dwelling species (such as *S. fuscum*)
may be weaker, or absent, compared to lawn species. It is therefore important that the same species, or species type (e.g.,
lawn species as they likely have a broad HWT niche), are used if $\delta^{13}\text{C}$ values are employed as a proxy to infer changes in
HWT.

340

We also identified evidence that evapotranspiration (ET), and productivity (NPP) modify $\delta^{13}\text{C}$ values, although the effect of ET was weak and restricted to *S. magellanicum*. We expected a stronger relationship as ET and temperature control $\delta^{13}\text{C}$ by increasing water loss at the moss surface and reducing the diffusive resistance (i.e., reducing CO_2 limitation), enabling **increased** discrimination against ^{13}C (Williams and Flanagan 1996). NPP only explained a small proportion of the variation in $\delta^{13}\text{C}$ values but the relationship was apparent across species. Several studies have proposed the use of $\delta^{13}\text{C}$ values to infer *Sphagnum* productivity (e.g., Rice and Giles 1996, Rice 2000, Munir et al. 2017) and our study is the first to test this at the pan-Holarctic scale. Deane-Coe et al. (2015) investigated $\delta^{13}\text{C}$ values across moss species (including *Sphagnum*) and years at one site and found a weak relationship between productivity and $\delta^{13}\text{C}$ values ($R^2=0.10$ and 0.31 , respectively). Similarly, Rice (2000) reported that relative growth rate explained about 25% of the variation in ^{13}C discrimination. We did not find as strong a relationship ($R^2 < 0.12$), but our study was geographically broader and less controlled; consequently, our results were likely influenced by more complex interactions among environmental factors that affect *Sphagnum* growth across our sites. Nevertheless, our results indicate independent effects of evaporation and productivity on $\delta^{13}\text{C}$ values. The lack of a strong NPP pattern somewhat limits the ability to infer productivity of *Sphagnum* in paleoecological studies.

4.2 Global patterns of $\delta^{18}\text{O}$ values in *Sphagnum*

Modelled $\delta^{18}\text{O}$ values in precipitation (Bowen 2010) explained much of the variation in $\delta^{18}\text{O}_{\text{tissue}}$ values between sites ($R^2=68\%$ for annual mean $\delta^{18}\text{O}_{\text{precip}}$). The percent variance explained was even higher if the spring period for modelled $^{18}\text{O}_{\text{precip}}$ was used, but lower for the growing season average. This result does not necessarily mean that spring season water was utilised by the plants during the growing season. Between-site variation in $^{18}\text{O}_{\text{precip}}$ values are much larger in the winter (Figure S1, see end of document), more effectively discriminating maritime and continental regions (Bowen 2010). The better fit may simply be an effect of a more distinct separation of $^{18}\text{O}_{\text{precip}}$ in the winter data. Although the $\delta^{18}\text{O}_{\text{tissue}} - ^{18}\text{O}_{\text{precip}}$ relationship presented here is robust, a few $\delta^{18}\text{O}$ values are less well-predicted by the regression model and they originate from Northwest Territories (Canada) and West Siberia (Russia). Likely, this suggests that the $^{18}\text{O}_{\text{precip}}$ model is less accurate in these interior regions with fewer **precipitation** collection stations.

In contrast, the data did not support a negative correlation between precipitation amount and $\delta^{18}\text{O}_{\text{tissue}}$ values and $\delta^{18}\text{O}_{\text{tissue}}$ values were only weakly affected by predictors associated with water loss (ET/P and/or temperature) and species identity. The indication of ^{18}O enrichment in *S. magellanicum* due to ET/P was expected as the lighter isotope ^{16}O needs less energy to vaporize. However, the opposite trend was suggested for *S. fuscum*, and surprisingly, higher surface temperatures decreased ^{18}O enrichment. Hence we conclude that climatic variables associated with water loss were weak predictors after controlling for $\delta^{18}\text{O}_{\text{precip}}$ values. This result may not be too unexpected as laboratory experiments have so far failed to relate ^{18}O enrichment in *Sphagnum* to differences in evaporation rates (Brader et al. 2010).

There have been few regional studies on moss $\delta^{18}\text{O}_{\text{tissue}}$ values that span gradients of $\delta^{18}\text{O}_{\text{precip}}$ values (Royles et al. 2016, Skrzypek et al. 2010) and most interpretations of moss $\delta^{18}\text{O}_{\text{tissue}}$ - climate relationships come from peat core studies (e.g. van der Knaap et al. 2011). In antarctic non-*Sphagnum* peat banks variation in $\delta^{18}\text{O}_{\text{cellulose}}$ values tracked $\delta^{18}\text{O}$ values in moss water across a latitudinal gradient (61°S-65°S) despite a lack of difference in $\delta^{18}\text{O}_{\text{precip}}$. This result led Royles et al. (2016) to suggest that moss water and tissue $\delta^{18}\text{O}$ values are better temporal integrators of source water than point rainfall measurements. The authors interpreted site-to-site differences as relating to differential evaporative enrichment and other physio-chemical factors that affect ^{18}O exchange, fixation and biochemical synthesis. Skrzypek et al. (2010) explored variation in *Sphagnum* $\delta^{18}\text{O}_{\text{tissue}}$ values across a regional altitudinal gradient and found no consistent trend or significant relationship linking $\delta^{18}\text{O}_{\text{tissue}}$ values to altitude, where $\delta^{18}\text{O}$ in source water is expected to differ. Although fractionation in source water caused by adiabatic cooling with altitude should lead to altitudinal effects, differences in precipitation amount can confound this pattern (Gat et al. 2000). Unfortunately, there are limited regional studies that have tested the effects of variation in source water on $\delta^{18}\text{O}_{\text{tissue}}$ values. Similar patterns may also occur along elevational gradients as $\delta^{18}\text{O}_{\text{tissue}}$ values are consistent with expected isotopically heavier source water at high elevations controlling tissue signals, but with small sample sizes (n=7) patterns remain unclear (Skrzypek et al. 2010). The present study provides a much greater range of geographical and environmental variation, and shows strong support for arrives at similar conclusions — $\delta^{18}\text{O}_{\text{tissue}}$ values in *Sphagnum* strongly tracking source water.

Interestingly, the relationship between $\delta^{18}\text{O}_{\text{tissue}}$ and $\delta^{18}\text{O}_{\text{precip}}$ values detected here is very similar to that proposed some time ago by Epstein et al. (1977); $\delta^{18}\text{O}_{\text{cellulose}} = 27.33 + 0.33 \times \delta^{18}\text{O}_{\text{precip}}$ [note that Jones et al. 2014 show high correspondence between $\delta^{18}\text{O}_{\text{cellulose}}$ and $\delta^{18}\text{O}_{\text{tissue}}$ values]). However, our data suggest a slightly steeper slope and lower intercept, particularly for *S. magellanicum*. The species effect on $\delta^{18}\text{O}$ suggests a difference in the degree of evaporation from the plant surface prior to uptake of water. The lower $\delta^{18}\text{O}$ values for *S. magellanicum* compared to *S. fuscum* (-0.83‰) is comparable to the results from bogs in Canada for the same species (-2.2‰, Aravena and Warner 1992) and between a hollow and a hummock species in The Netherlands (-2‰, Brenninkmeijer et al. 1982). This suggests that the absorbed water in this *S. magellanicum* was subject to less evaporation. In *Sphagnum* plants, surface water is largely affected by capillarity, water storage and reducing conductance with compact morphology. Plant traits that enhance these functions are more pronounced in species and individuals found at high HWT as these characteristics maintain high tissue water content (Hayward and Clymo 1982, Laing et al. 2014, Waddington et al. 2015). Consequently, during droughts, *Sphagnum* species growing close to the water table will dry out quickly as the evaporative demand cannot be balanced, and simultaneously photosynthesis is shut down. *Sphagnum* species higher above the water table wick water from below and store water effectively, thereby remaining photosynthetically active while water is lost due to evaporation. This mechanism would result in ^{18}O enrichment being higher above the water table (Brenninkmeijer et al. 1982, Aravena and Warner 1992), and explains the positive relationship between HWT and $\delta^{18}\text{O}$ in *S. magellanicum* reported by Loader et al. (2016) along a 10 m transect. We found a weak positive relationship of $\delta^{18}\text{O}$ with HWT, which suggests that HWT cannot entirely explain species-specific differences in ^{18}O

enrichment. Instead, this can be attributed to lower water retention (i.e. higher evaporation at the same water deficit) in *S. magellanicum* compared to *S. fuscum* (Clymo 1973, McCarter and Price 2014). Although species differences in ^{18}O have been reported (Aravena and Warner 1992, Zanazzi and Mora 2005, Bilali et al. 2013), our study suggests that the species-specific $\delta^{18}\text{O}$ signals may not simply be a consequence of growing at different HWT but can rather reflect distinct water retention capacity in these species.

The strong influence of $\delta^{18}\text{O}_{\text{precip}}$ values and, to a much lesser extent, environmental variables related to water loss, combined with a relatively small within-site variation in $\delta^{18}\text{O}_{\text{tissue}}$ values, suggest that macroclimatic drivers, such as precipitation inputs, largely determine the $\delta^{18}\text{O}$ value of peatland moss tissue. These results are promising for the use of oxygen isotopes in large-scale paleoecological reconstructions from peat cores (Ellis and Rochefort 2006, Chambers et al. 2012, Daley et al. 2010), although a better understanding of O isotope fractionation within tissue components and their decay relationships would improve their utility. Moreover, the simple relationships presented here can potentially be utilised to trace changes in $\delta^{18}\text{O}_{\text{precip}}$ values that mirrors climate variability.

420 **5 Conclusions**

Our study provides new insights into large-scale variation in *Sphagnum* tissue isotopic signature and suggests that isotopic composition can be used for climatic reconstructions. We show a close link between precipitation and tissue $\delta^{18}\text{O}$ values and conclude that variation in $\delta^{18}\text{O}$ values are mainly driven by the macroclimate, but species differences exist. In contrast, $\delta^{13}\text{C}$ values were strongly related to local microtopography while the influence of macroclimate was negligible. As suggested in earlier studies, $\delta^{13}\text{C}$ values were also weakly associated with NPP. These conclusions were most strongly supported for the cosmopolitan *S. magellanicum* complex and species identity should be accounted for in future carbon isotope studies to avoid spurious conclusions.

6 Data and code availability

430 Data and R-script to reproduce results are available at Figshare, <https://dx.doi.org/10.6084/m9.figshare.6969497> for review at <https://github.com/ggranath/isotopeSphagnum>. Upon acceptance these files will be moved to a permanent public repository.

				Within-site		Between-site	
	Species	N _{site}	N _{obs}	Std. Dev.	Proportion variance (%)	Std. Dev.	Proportion variance (%)
$\delta^{13}\text{C}$	<i>S. fuscum</i>	80	169	0.9	56	0.8	44
	<i>S. magellanicum</i>	83	168	1	51	0.98	49
$\delta^{18}\text{O}$	<i>S. fuscum</i>	80	168	0.7	13	1.83	87
	<i>S. magellanicum</i>	83	167	0.67	10	2	90

Table 1. Sample sizes, standard variation and overall partitioning of measured variation for each species and response ($\delta^{13}\text{C}$ and $\delta^{18}\text{O}$). N_{site} is the number of sites and N_{obs} the total sample size. Standard deviation of the responses is given for within and between sites, together with the proportion of total variance measured between sites and within sites.

*The effect of *S. magellanicum* compared to *S.fuscum* at HWT 28 cm.

495 Table 2. Results from linear mixed-models for $\delta^{13}\text{C}$ values. Statistical tests are based on type-2 *F*-test using Kenward-Roger
adjusted degrees of freedom. The second model only included *S. magellanicum*. Elevation [m asl] and the three climatic variables
(growing season sums and means: ET/P, P [mm], temp [°C]) were tested one by one in the model including HWT [Height above
the Water Table, cm], species and NPP [$\text{g m}^{-2} \text{year}^{-1}$]. For simplicity, the negligible HWT \times NPP term was dropped from this model
(P = 0.36). Estimated effects (+/- SEs) are only given for main effects if interactions were considered negligible. These effects are
500 slopes for continuous variables (all variables except species) and for species (categorical) the difference between *S. magellanicum*
and *S. fuscum* (i.e. *S. fuscum* being the reference level). In the presence of an interaction between HWT and species, the species
effect was estimated at mean HWT. R^2_{site} = explained between-site variance, R^2_{marginal} = explained total variance.

505 Table 3. Results from linear mixed-models for $\delta^{18}\text{O}$ values. Statistical tests are based on type-2 *F*-test using Kenward-Roger
adjusted degrees of freedom. Three time periods for modelled $\delta^{18}\text{O}$ values (‰) in precipitation were tested individually: annual
mean, growing season (Apr-Sep) and spring (Jan-Apr). The three climatic variables (growing season sums and mean: ET/P, P
510 [mm], temp [°C]) were tested one by one in a model including HWT [cm] and mean annual $\delta^{18}\text{O}$ values). Estimated effects (+/-
SEs) are only given for main effects if interactions were considered of negligible. These effects are slopes for continuous variables
(all variables except species) and for species (categorical) the difference between *S. magellanicum* and *S. fuscum* (i.e. *S. fuscum*
being the reference level). R^2_{site} = explained between-site variance, R^2_{marginal} = explained total variance.

545

550

Figure 2. Relationship between height above the water table (HWT, measured at the end of the growing season) and $\delta^{13}\text{C}$ values in two *Sphagnum* species sampled across the Holarctic realm. **Pale lines represent relationships for individual sites, while thicker H lines show the pooled regression line in a mixed-effect model. Shaded areas indicate approximate 95% confidence intervals ($2 \times \text{SE}$) of the regression coefficients that do not include the uncertainty of the random effects.** Equations: *S. fuscum*, $\delta^{13}\text{C} = -27.56 - 0.021 \times \text{HWT}$; *S. magellanicum*, $\delta^{13}\text{C} = -27.74 - 0.045 \times \text{HWT}$. $N_{\text{site}} = 83$, $N_{\text{total}} = 311$. See also Table 1.

555

Figure 3. Association between modelled annual mean $\delta^{18}\text{O}_{\text{precip}}$ values and $\delta^{18}\text{O}$ values in two *Sphagnum* species. Data show predicted-site means for each species and error bars represent the standard deviation (at some sites only one sample of a species was takenBLUPs) and error bars represent the approximate 95% confidence intervals ($2 \times \text{SE}$). Regression lines with different intercepts ($P < 0.001$, Table 2) illustrate the relationship between modeled $\delta^{18}\text{O}_{\text{precip}}$ and *Sphagnum* $\delta^{18}\text{O}$. Equations: *S. fuscum*, $26.36 + 0.43 \times \delta^{18}\text{O}_{\text{precip}}$ ($n = 1-2$, $N_{\text{site}} = 80$); *S. magellanicum*, $25.53 + 0.43 \times \delta^{18}\text{O}_{\text{precip}}$ ($n = 1-2$, $N_{\text{site}} = 83$). Shaded areas indicate approximate 95% confidence intervals ($2 \times \text{SE}$) of the regression coefficients that do not include the uncertainty of the random effects.
