Abstract. Viruses have been acknowledged to be important components of the marine system for the past two decades, but their role in the functioning of the geochemical cycle has not been thoroughly elucidated to date. Virus induced rupturing of cyanobacteria is theoretically capable of releasing intracellular bicarbonate and inducing the homogeneous nucleation of calcium carbonate; however, experiment-based support for virus induced calcification is lacking. In this laboratory study, both water carbonate chemistry and precipitates were monitored during the viral infection and lysis of host cells. Our results show that viral lysis of cyanobacteria can influence the carbonate equilibrium system remarkably and promotes the formation and precipitation of carbonate minerals. Amorphous calcium carbonate (ACC) and aragonite were evident in the lysate, compared to the brucite precipitate in noninfected cultures, implying that a different precipitation process had occurred. Based on the carbonate chemistry change and microstructure of the precipitation, we propose that viral lysis of cyanobacteria can construct a calcification environment where carbonate is the dominant inorganic carbon species. Numerous virus particles available in lysate may coprecipitate with the calcium carbonate. The experimental results presented in this study, first demonstrate the pathway and result regarding how viruses influence the mineralization of carbonate minerals. Furthermore, our results also imply that viruses play a crucial role in seawater carbonate chemistry and may balance the geochemical element budget within the earth system.

1 Introduction

Over the past several years, several studies have highlighted the urgent need to better understand the changes in seawater carbonate chemistry, which is one of the fundamental processes in the carbon cycle on both the global and regional scales. This is mainly because it is the primary buffer for the acidity of water in the earth-surface environment (Ridgwell and Zeebe, 2005; Martin, 2017; Zeebe, 2012). The ocean is recognized as a large carbon reservoir that contains approximately sixty times more carbon in the form of dissolved inorganic carbon than that in the pre-anthropogenic atmosphere (Zeebe and Wolf-Gladrow, 2009). Dissolved inorganic carbon in typical surface seawater, with a pH of 8.2, is occurs mainly in the form of...
$	ext{HCO}_3^-$, compared to the speciation of $	ext{CO}_3^{2-}$ and $	ext{CO}_2$, with a ratio of 89 : 10.5 : 0.5 (Zeebe and Wolf-Gladrow, 2009). Formation and dissolution of calcium carbonate is one of the most important processes that can change carbonate chemistry in seawater (Equation 1).

$$\text{Ca}^{2+} (\text{aq}) + 2\text{HCO}_3^- (\text{aq}) \rightleftharpoons \text{CaCO}_3 (s) + \text{CO}_2 (\text{aq}) + \text{H}_2\text{O} \quad (1)$$

Modern sea water is considered supersaturated with several calcium carbonate phases, such as calcite and aragonite. However, there is no persistent precipitation of calcium carbonate in sea water because of the inability to overcome the energetic threshold for homogeneous precipitation. Marine calcium carbonate mineral is traditionally considered to be calcification production of coral, coccolithophores, foraminifera or pteropods. The recent identification of an unaccounted fraction of marine calcium carbonate particles in seawater suggests that additional environmental factors affecting the formation of calcium carbonate should be further investigated (Heldal et al., 2012).

Cyanobacteria, which are ubiquitously abundant organisms and play important roles in most aquatic environments, are usually known to influence CaCO$_3$ precipitation by taking up inorganic carbon via photosynthesis (Obst et al., 2009b; Planavsky et al., 2009; Yang et al., 2016; Kamennaya et al., 2012; Kranz et al., 2010; Semesi et al., 2009; Riding, 2011; 2012; Merz-Preiß, 2000). Although there is great importance in calcium carbonate formation mediated by cyanobacteria in sedimentary deposits, the mechanisms involved are still controversial. In many cases, the precipitation of CaCO$_3$ by cyanobacteria has been invariably considered a noncontrolled process, promoted either by photosynthetic uptake of inorganic carbon, raising the pH adjacent to cyanobacterial cells (Riding, 2006) or induced by cell-surface properties for the nucleation of CaCO$_3$ minerals (Obst et al., 2009b). In contrast, diverse cyanobacterial taxa have been shown recently to form amorphous calcium carbonate minerals intracellularly, with a diameter of several hundreds of nanometers (Couradeau et al., 2012; Benzerara et al., 2014). The intracellular carbonate makes the mechanisms involved in calcification more confusing (Cam et al., 2015; 2016; 2018; Li et al., 2016). Thus, new pathways, in which some biological processes alter the carbonate system, are important to evaluate.

Viruses, which are vital parasites of unicellular cyanobacteria, can modulate microbial production and, in some cases, can terminate plankton blooms (McDaniel et al., 2002; Bratbak et al., 1993; Bratbak et al., 1996; Suttle, 2005; 2007). It has been established that 3-31% of free-living bacteria are infected by viruses, which can occur in excess of $10^5$ infectious units ml$^{-1}$ (Suttle and Chan, 1994). Hence, viral lysis of microbes is certainly thought to have direct effects on both ecosystem function involving the release of nutrients back into the environment and the host-involved geochemical reaction (Brussaard et al., 2008; Rohwer and Thurber, 2009; Weitz and Wilhelm, 2012; Jover et al., 2014).

The thermodynamic calculation proposed by Lisle and Robbins (2016) infers that virus induced cyanobacteria lysate theoretically can elevate the saturation index of carbonate minerals at the cellular level, by releasing cytoplasmic-associated bicarbonate. This thermodynamic calculation also highlights that the released cytoplasm-associated bicarbonate can be as much as $\sim23$-fold greater than in the surrounding seawater, which can shift the carbonate chemistry toward the homogenous nucleation of calcium carbonate (such as vaterite). However, theoretical calculations do not take into account the condition
that magnesium may influence the properties and behaviors of carbonate in seawater (Morse et al., 2007). Displacements of acid-base carbonic equilibrium in seawater can not only form calcium carbonate minerals, but also can lead to the precipitation of Mg(OH)$_2$ (brucite) (Möller, 2007). It has been proposed that the dissolution of brucite in seawater is favourable for CaCO$_3$ precipitation (Nguyen Dang et al., 2017).

Furthermore, viral particles could act as nucleation sites for precipitation of different minerals. In the past few years, researchers have investigated the theory that the capsid of viruses can interact directly with elements in solution, and thus, potentially mediate the formation and precipitation of different minerals (Daughney et al., 2004; Kyle et al., 2008; Peng et al., 2013; Pacton et al., 2014; De Wit et al., 2015; Laidler and Stedman, 2010; Orange et al., 2010). Virus-related carbonate minerals are also reported in recent studies of biofilms from hypersaline lakes, where hypersaline carbonate minerals can precipitate at the surface of viral particles (Pacton et al., 2014; Lisle and Robbins, 2016; Perri et al., 2017). However, the pathway of precipitation of calcium carbonate onto the surface of viruses remains poorly understood. When combined with the release of cytoplasm-associated bicarbonate, which results in the formation of carbonate mineral energetically favored, and available viral capsids for surface-induced precipitation, the comprehension of viral influence on the precipitation of carbonate is extremely limited.

Laboratory studies of viral calcification were adopted here by culturing viruses and their host Synechococcus spp. PCC 7177. Such modeling experiments do not intend to mimic the processes occurring within the cells, which remain unknown, and generally do not provide an ultimate and direct answer as to which geobiological processes are involved in biomineralization. However, these experiments constrain, to some extent, the chemical conditions necessary to predict the geochemical processes similar to those in the aquatic environment. Carbonate parameters and cultural status were monitored to calculate the carbonate equilibrium system and saturation index. Precipitates of the culture were also characterized, to identify the microstructure of the minerals. Our results provide large-scale support of the importance of carbonate formation and precipitation during virus induced cyanobacteria mortality in the marine system. The extension of the viral role in mediating sea water carbonate systems will also provide an important, but previously ignored, carbon cycle in the earth system.

2 Methods and Materials

2.1 Cyanobacteria and Viruses

Cyanobacteria, which have a long evolution history and are widespread in the marine environment, are key primary producers in the surface of the world ocean system. Synechococcus sp. PCC 7177 and the viruses that infected it were isolated from surface seawater from Sanya Bay (Supplement material). Synechococcus is a unicellular cyanobacterium that is very widespread in the marine environment and thus, is well-adapted for the present experiment (Fig. S1). Isolated virus particles, which are ~53 nm in diameter (Fig. S2), are classified as podovirus, based on morphology and metagenomic analysis (Fig. S3).
2.2 Culture conditions and calcification experiments

Cyanobacteria and viruses were grown at 25°C, under a photon irradiance of 6000 lux, with a 12 h light/dark cycle. Before the precipitation experiments, cyanobacteria were cultivated to harvest fresh cells for calcification experiments. Precipitation experiments were performed in sterile 4-L borosilicate bottles, in 0.2-µm-filtered artificial medium (based on F/2 media, Table 1). To minimise gas exchange with air, filtration was performed by means of a peristaltic pump. To avoid artifacts caused by residues from previous precipitation experiments, the bottles were treated overnight in 0.1 M hydrochloric acid, rinsed with water several times and finally, stored overnight filled with water. 2000 ml of medium was added into each bottle. The headspaces of the bottle were continuously exchanged with ambient air via a plastic membrane. The inoculation and subsampling of each experiment was performed aseptically.

Two milliliters of fresh cells from the precultures was inoculated into each of 2 L of culture media. After the lag phase (day 5), 5 ml of viral stock (~10^9 virus particles per milliliter) was inoculated in one treatment (Group A) to detect the potential viral influence on carbonate chemistry. The other treatment without inoculation of viruses was left as a control (Group B). Both treatments were run in duplicate, and subsamples from these incubations were taken simultaneously over the course of the incubations.

During the course, subsamples were taken from both treatments for analysis of the cell and virus concentration, total alkalinity (TA), dissolved inorganic carbon (DIC), calcium and magnesium concentration, and morphology of minerals. First, salinity was determined by measuring the apparent electrical conductivity. Cells and viruses were enumerated with a 1.5 ml solution. Filtrates (through 0.22 µm filters) were collected for TA, DIC, calcium and magnesium analysis. TA samples (30 ml) were stored in borosilicate bottles at room temperature. DIC samples (5 ml) were stored in borosilicate flasks without headspace at 4 °C. Subsamples for DIC and TA were poisoned with HgCl₂ solution to inhibit growth (Cao and Dai, 2011). At the end of the stationary phase (day 16), the particulate fraction of the medium (~1 L) was harvested via centrifugation (13000 g, 5 min) for electronic microscopy and X-ray diffraction study, using the methods adopted from Peng et al. (2013).

2.3 Measuring methods

2.3.1 Total alkalinity and dissolved inorganic carbon

Total alkalinity (TA) was determined by titration of 25.00 ml of medium samples with HCl solution from the volume of HCl required. The instrument and program ran automatically by Metrohm 916 Ti-Touch. The approximately 0.1 N HCl solution was ascertained by titration of solutions made from dried high-purity sodium carbonate and borax. The fluctuations of our total alkalinity determinations were approximately limited to 10 µM/kg.

DIC was measured by acidification of 0.5-1.0 ml of water samples at the Stable Isotope Laboratory, Third Institute of Oceanography, State Oceanic Administration, China. Measurements were performed with continuous flow isotope ratio mass spectrometry (Delta V Advantage, Thermo-Fisher Scientific Inc., USA), coupled with a GasBench II device.
2.3.2 Calcium and magnesium cations
Concentration of magnesium and calcium cations were determined by ion chromatography (Dionex ICS-900), after acidification by 1 N HCl. The precision of the IC method used was 2 ppm for Ca\(^{2+}\) and 5 ppm for Mg\(^{2+}\).

2.3.3 Enumeration of cells and viruses
For determination of cell numbers, samples of 0.5ml were filtered on black nuclepore filters (25 mm, 0.2μm pore size, Whatman) under low vacuum (200 mbar). Cyanobacteria were counted within 72h under a Leica fluorescence microscope (Leica DM6B) with autofluorescence. The growth curves of the cultures were drawn through constant survival cell counts.

Enumeration of viruses from the culture was following Patel et al., (2007). Subsamples were first filtered (25 mm, 0.2μm pore size, Whatman) to remove bacteria and large mineral particles. Aliquots of filtered supernatant were filtered through 0.02μm poresize Anodisc 25 membrane filter (Whatman, Inc.). The Anodisc filters were then stained with a final concentration of 25X SYBR Green for 15 min, mounted on glass microscope slides, and treated with an antifade solution. The slides were examined using an epifluorescence microscope (Leica DM6B) within 72 h. A minimum of 10 fields of view was examined per slide.

2.3.4 Electronic microscopy
Subsamples for the TEM study were fixed by the addition of glutaraldehyde (to 4% final concentration); they were then rinsed in distilled water to remove salts, mounted on copper grids and air-dried. The TEM analysis was conducted on a JEM-2100F field emission electron microscope operated at an accelerating voltage of 200 kV. Elemental analysis was conducted at 200 kV using an Oxford INCA Energy TEM X-ray energy dispersive spectrometer. Elemental maps were acquired in a STEM DF mode operating at 200 kV, with a focused electron beam (1 nm). The mineralogy of the structures in the areas of interest were determined using selected-area electron diffraction (SAED).

For SEM analysis, dried precipitates were fixed onto aluminum stubs with two-way adherent abs and allowed to dry overnight. The samples were carbon-coated and examined with an Apreo scanning electron microscope (Thermofisher Scientific).

2.3.5 X-ray Diffraction
XRD was employed to characterize the bulk mineralogy of the precipitates. The subsamples were thoroughly ground, followed by analyses using a LabX XRD-6100 X-ray Diffractometer with Cu Kα radiation (λ = 1.54056 nm) and a 2θ angle in the range of 10° to 80° at a speed of 1° min\(^{-1}\).

2.4 Saturation indices calculation
To determine the activity of the carbonate species and the degree of saturation in the solutions sampled, the geochemical computer program PHREEQC Interactive [version 3.3; Wateq4f database; United States Geological Survey (USGS), Reston, VA, USA] was used. The saturation index (SI), defined as SI = log Ω = log[ IAP/K\(_{sp}\) Mineral], where IAP is the ion activity product (For CaCO\(_3\), IAP= [Ca\(^{2+}\)][CO\(_3^{2-}\)]) and K\(_{sp}\) represents the solubility product for a given temperature, was also calculated.
with PHREEQC. Although PHREEQC is more convenient for calculating magnesium-related minerals, we also used CO2Cal [version 4.0.9; United States Geological Survey (USGS), Reston, VA, USA] to calculate the carbonate system for comparison.

3 Results

3.1 Growth of cyanobacteria culture

The color of the culture medium varied daily between the two treatments after virus induced lysis. The supernatant of Group A, which was inoculated to allow the adsorption and infection of cyanobacteria, became clarified on the 14th day and seemed completely clear on the 17th day (Fig. 1b, d). Group B, in contrast, had some turbidity and higher cell density at the corresponding times (Fig. 1a, c). By the time cells were lysed, the white precipitation phase emerged in Group A (Fig. 1b, d).

Cell growth was monitored over the course of 20 days by counting the autofluorescence of cyanobacteria. After the inoculation, cells exhibited a lag phase and started to grow exponentially for 9 to 13 day before reaching maximum cell numbers (Fig. 2a).

The cell abundance of Group A was slightly lower than Group B on the fifth day to eighth day (Fig. 2a). Although the cell abundance increased at the first few days, the growth rates of Group A were slightly lower and the cell number was reduced to $1.7 \times 10^7$ cell/ml, compared to the $1.3 \times 10^8$ cell/ml of Group B (days 19, Fig. 2a). The maximum number of virus particles occurred on the 9th day (Fig. 2a). Unlike the traditional viral one-step growth curve, virus particle in the present calcification experiment decreased with the ongoing process of calcification.

3.2 Change of carbonate parameters

The carbonate chemistry of the two treatments showed similar patterns during the first 10 days, but started to deviate strongly in terms of the total alkalinity (TA) and dissolved inorganic carbon (DIC) afterwards, when the cell lysis rates were greater than cell replication rates in Group A (Fig. 2b, c). As DIC transportation by the growth of cyanobacteria, there was a negative correlation between DIC and cell growth in Group B (Fig. 2a, c). When cultures were at the end of the exponential phase (Group B, days 14), the DIC declined to the lowest values. In group A, by contrast, the lowest DIC values was found on the 12th day, when the lytic rate began to dominate cell replication. DIC then rose to the initial level, because of re-equilibration with the atmosphere in the present open system. The TA of the two treatments also dropped during the exponential phase, reflecting a removal of cations from the solution (Fig. 2b). Compared to Group A, TA in Group B dropped to the lower level.

During the lytic phase in Group A, TA increased again to values of $2936 \ \mu$mol/kg in three days and maintained balance during the lytic cycle. Both calcium and magnesium cations were removed from the solution at the early-exponential growth phases (Fig. 3). It is interesting to find that precipitated calcium redissolved into the solution in Group B. In striking contrast, there was a persistent calcium removal within the viral lysate, indicating that robust virus-induced calcification had occurred (Fig. 3 a, b).
3.3 Microstructure of virus-induced carbonate precipitation

SEM and TEM images of the white precipitates from the viral lysate showed numerous calcium nanoparticles scattered or aggregated. These particles were in a spherical morphology, having diameters ranging from dozens of nanometers to hundreds of nanometers (Fig. 4, 5). STEM mappings and XEDS analysis showed evidence of calcium accumulation all around the particle surface (Fig. 5), as well as selected-area electron diffraction (SAED) patterns with diffuse halos (Fig. 5b), confirming that they were amorphous calcium carbonate (ACC) (Rodriguez-Blanco et al., 2008). Although Mg was not dominant in the particles, there were signs of enrichment of Mg around the particles (Fig. 5c). SEM images of the nanoparticle are attached to the surface of the infected cells and usually have an encrusted structure (Fig. 4d). The bulk mineralogy of the cultural deposits, based on XRD analyses, were dominated by brucite in the noninfection treatment, compared to aragonite in the lysate (Fig. 6).

4 Discussion

4.1 Carbonate chemistry influenced by the growth of cyanobacteria

Various studies in recent years have demonstrated the direct effects of carbonate chemistry shifts over the course of cyanobacteria growth (Dittrich et al., 2003; Kranz et al., 2010; Millo et al., 2012; Obst et al., 2009b; Yang et al., 2016). In cases where photosynthesis occurred, this results in the stimulation of cell division and DIC uptake, but no total alkalinity changes because no other sources of base are added during photosynthetic carbon uptake:

\[ HCO_3^- + H_2O \rightarrow CH_2O + OH^- + O_2 \]  \hspace{1cm} (2)

Studies of cyanobacteria calcification always attribute the increase of pH to the growth of cyanobacteria which construct a favorable calcification environment where carbonate is the dominant inorganic carbon species and induces calcification by the incorporation of carbonate ions into a growing CaCO$_3$ crystal (Lee et al., 2004; Obst et al., 2009a; Kranz et al., 2010). It has been interpreted by the majority of studies that cyanobacteria calcification is restricted to certain species (Merz-Preiß, 2000; Lee et al., 2004). The calcification induced by photosynthetic acid-base equilibrium by *Synechococcus* sp. PCC 7177 in the present study seems to be transitional and unable to calcify to the extent that stable CaCO$_3$ precipitates are formed. This is inferred based on the observation that cations are released again into the solution in Group B. Fixed Ca$^{2+}$ redissolves to the concentration equivalent to the former concentration (Fig. 3a). On the 8th day, however, there was an evident decrease in calcium concentration, accompanied by a decrease of TA, which implies that calcium carbonate was formed and separated from the filtrate (Fig. 3a). Photosynthetic carbon uptake (Equation 2) raised the pH values of the medium, leading to the formation of CaCO$_3$. This CaCO$_3$ phase can be recognized as amorphous calcium carbonate, based on electron microscope images (Fig. 4, 5) and the fact that it is unstable. ACC, which received relatively little attention as one of metastable CaCO$_3$ phases, has been increasingly recognized as a precursor for the formation of crystalline calcium carbonate (Cartwright et al., 2012; Weiner and Addadi, 2011). ACC may precipitate virtually instantaneously, when conditions promote high local supersaturation for short periods of time (Blue et al., 2017; Cartwright et al., 2012). Although the saturation index (SI) of the
ACC < 0 (Table 2), implying nonspontaneous ACC formation within the solution, the growth of cyanobacteria in the present experiment created an ACC favorable microenvironment on days 8-10, reflected by the removal of Ca$^{2+}$. Magnesium, which is actually precipitated as brucite from the solution, is also responsible for removing TA from the cyanobacteria culture. It has been demonstrated that supersaturated Mg(OH)$_2$ can precipitate at local alkaline conditions with pH > 9.30 (Möller, 2007). Saturation indices (SI), which are determined using the software PHREEQC, yielded values > 0 for brucite (Mg(OH)$_2$) during the first 8 days (0.34 ~ 1.15) and values < 0 after the 10th day (-1.47 ~ -0.15) in Group B (Table 2). As DIC transportation by cyanobacteria proceeded, the pH of the growth medium increased (Table 2, S1), thus, leading to the formation of Mg(OH)$_2$ in the supersaturated state (Equation 2 and 3). The emergence of brucite crystal formation have also been reported in coral microbial biofilms (Nothdurft et al., 2005) and cultures of diatoms (Tesson et al., 2008), where high pH and low pCO$_2$ microenvironments are created by biological activities such as the cyanobacteria in the present study (PCO$_2$ data can be found from the Table S1, calculated by CO2Cal).

$$\text{Mg}^{2+} + 2\text{OH}^- \rightarrow \text{Mg(OH)}_2 \tag{3}$$

Upon the mass consumption of DIC by photosynthesis and fixation of calcium, cell growth seems to slow down (days 8-9, Fig. 2a). In the present open system, atmospheric CO$_2$ is dissolved in water and changes the acid-base balance of the system. Dissolved carbon is present in the form of bicarbonate at the present pH level:

$$2\text{CO}_2 + \text{CO}_3^{2-} + \text{OH}^- + \text{H}_2\text{O} \rightarrow 3\text{HCO}_3^- \tag{4}$$

The reaction represented by equation 4 in Group B, based on the continuous decrease of DIC (days 10-14). On days 9 ~ 10, there is an insufficient amount of carbon for photosynthetic carbon to be concentrated in the form of CO$_2$ or HCO$_3^-$ (Miller et al., 1990). Nevertheless, cyanobacteria grew vigorously during days 10-14 (Fig. 2a). The consumption of CO$_3^{2-}$ and OH$^-$ led the unstable minerals, such as ACC and brucite, to dissolve in the solution. Especially for the ACC, robust carbon concentration inhibits the transformation of ACC to a more stable carbonate phase such as aragonite. pH values calculated by PHREEQC after the 10th day were reduced to 8.66, at which Mg(OH)$_2$ formation cannot occur spontaneously. Consequently, with the growth of cyanobacteria, carbonate alkalinity limitation leads to the redissolution of calcium and magnesium minerals.

### 4.2 Carbonate chemistry influenced by viral lysis of cyanobacteria

It seems that the two treatments of the tested culture grew at similar rates and reached similar cell densities during the first 8 days, despite inoculation with the viruses (Fig. 2a). However, when lytic rates ran over the bacterial replication (day 8), Mg$^{2+}$ began to recover to the initial level, but Ca$^{2+}$ was further removed simultaneously presenting distinct variations between the two treatments.

In regard to magnesium, which is immobilized from the solution in the form of brucite, the resulting mineral grains are unstable. It has been suggested that brucite may not be preserved over longer time frames, possibly being dissolved in the
undersaturated state (Nothdurft et al., 2005). There is a strong positive correlation between Mg$^{2+}$ and DIC recovered after the 12$^{th}$ day in Group A, which is the time point when the lytic rate begins to dominate cell replication. In the present open system, atmospheric CO$_2$ is dissolved in water and changes the acid-base balance of the system. Hence, brucite can dissolve with acidification during the culture of cyanobacteria:

\[
\text{Mg(OH)}_2 + \text{CO}_2 \rightarrow \text{Mg}^{2+} + \text{HCO}_3^- + \text{H}_2\text{O}
\] (5)

The release of extra bicarbonate releasing during the dissolution of brucite also contributes to the TA recovery after the 12$^{th}$ day.

On the other hand, it should be noted that, with the aid of the virus, photosynthetic uptake of inorganic carbon decreases. Calcium, which is in the form of ACC during the growth of cyanobacteria, is formed in a stable carbonate environment, where Equation 4 cannot take place (days 8-12). The atmospheric CO$_2$ exchange is neutralized by Mg(OH)$_2$, as discussed above (days 12-16). Brucite dissolution in seawater controls the pH and Mg/Ca ratios and is recognized as a key factor inhibiting calcite and vaterite growth and precipitation (Nguyen Dang et al., 2017). Thus, a microenvironment favorable for calcification is available after the viral lysis of cyanobacteria and deposition of aragonite carbonate minerals.

4.3 Virus induced carbonate precipitation

The aggregates of aragonite in viral lysate were confirmed by the means of XRD (Fig. 6). It has been extensively investigated that various physicochemical factors control the formation of the CaCO$_3$ polymorph and aragonite tends to precipitate under a high molar ratio of Mg/Ca (Folk, 1974; Berner, 1975). Nevertheless, the microenvironment maintained by the growth of *Synechococcus* sp. PCC 7177 could not overcome the activation energy barriers for the formation of aragonite, according to the evidence presented by XRD and the carbonate chemistry changes in Group B. TEM images revealed no order in the majority of the detected particles (Fig. 4, 5), which was confirmed by the diffuse rings in the selected area electron diffraction patterns and the appearance of nanodomains within the ACC particles (Rodriguez-Blanco et al., 2008). Unlike Group B, with the aid of the viral cycle and the lysis of the host, the dissolution of carbonate seemed not to occur, and a more stable mineral formed in Group A.

Here, a possible model for calcium carbonate precipitation induced by viral lysis of cyanobacteria is proposed regarding the carbonate chemical changes and microstructures (Fig. 7). As bicarbonate transport by cyanobacteria and intracellular conversion to CO$_2$ for photosynthesis proceeded, the pH of the ambient waters increased, leading to the formation of brucite and ACC. If no viruses were available, cell growth and replication would consume the bicarbonate. Atmospheric CO$_2$ dissolves in water but cannot do so in the form of CO$_2$ or HCO$_3^-$ for photosynthesis, because of the high pH. Alternatively, dissolved CO$_2$ reacts with OH$^-$ and Mg(OH)$_2$ resulting in dissolved carbon in the form of HCO$_3^-$ for cyanobacteria. However, when cells are infected by viruses, there are a few percentages of uninfected cells that require bicarbonate. Only Mg(OH)$_2$ dissolved to neutralize the dissolution of CO$_2$ and precipitation of calcium carbonate will continue.
Preliminary investigations have also demonstrated that viruses from hypersaline lakes are incorporated in biogenic carbonate, suggesting that viruses may be mistaken for nanobacteria and may play a role in initiating calcification (De Wit et al., 2015; Pacton et al., 2014; Perri et al., 2017). The viral drive during the biogenic carbonate precipitation in hypersaline lakes is attributed to either an indirect route, involving silicified viruses as an intermediate phase during diagenesis (Pacton et al., 2014) or a direct incorporation of amino acids polymerized with viral proteins into growing high-Mg calcite crystals (De Wit et al., 2015). The encrusted structure indicated by SEM images may support the hypothesis of carbonate formation on and near the virus particles (Fig. 4d). Coprecipitation of viruses and calcium carbonate is also supported by the number of viruses floating in the solution. Subsamples for enumeration of virus particles were filtered to remove precipitated minerals. The yield of the filtrate may preclude viruses incorporated in minerals. This is a reasonable explanation as to why virus numbers did not increase exponentially, despite the bursting of host cells (Fig. 2a). Viral infection does not result in the immediate lysis of the host cell; dormancy occurs, while integrating their genome with host DNA and the replication along with it is relatively harmless. When the reproductive cycle initiates, the virus attacks and breaks down the cell wall peptidoglycan, which is an essential structure that protects the cell protoplast from mechanical damage and from osmotic rupture (Middelboe and Jørgensen, 2006). Thus, we propose that Ca$^{2+}$ has unfettered access to the intracellular space and reacts with cytoplasmic alkalinity (Fig. 7). When Ca$^{2+}$ access to intracellular space, the existence of the capsid synthetized by viral DNA provides a surface for the initial calcification (Fig. 7). Calcification involves the addition of material to the preexisting viral surfaces, which may be similar to the mineralized virus in microbial mat from hot springs (Peng et al., 2013) or hypersaline lakes (Pacton et al., 2014; De Wit et al., 2015; Perri et al., 2017).

Viruses are vital parasites of unicellular marine cyanobacteria modulating microbial production and, in some cases, terminating plankton blooms (McDaniel et al., 2002; Bratbak et al., 1993; Bratbak et al., 1996). The pathway of virus-induced calcification during the lysis of the host cells was determined by experimental study and expands the roles of viruses in marine geochemical cycles. Owing to the fact that biologically mediated CaCO$_3$ precipitation is one of the fundamental processes in the carbon cycle (Ridgwell and Zeebe, 2005; Planavsky et al., 2009; Riding, 2011; Kamennaya et al., 2012), the study of viral impact is important in an understanding of the carbon cycling on both the global and regional scales. For example, so-called “Whiting events”, which refers to events of high levels of suspended, fine-grained CaCO$_3$ precipitation, have long been spectacular and extensively investigated CaCO$_3$ precipitation events due to their controversial origin (Wright and Oren, 2005; Morse et al., 2003). Clear evidence of net carbonate precipitation from the waters culturing cyanobacteria and viruses suggest that release of the virus during plankton bloom may stimulate virus-induced CaCO$_3$ precipitation, representing one potential whiting mechanism for CO$_2$ sequestration. Furthermore, in view of the marine virus-induced carbonate deposition and the increased Mg/Ca ratio of the medium (Fig. 3c), the possibility that viral processes alter seawater Mg/Ca rations, which are an important proxy for reconstructing the paleoenvironment (Lear et al., 2000), is thus important to evaluate.
5 Conclusion

First, we provide a detailed view of changes in carbonate chemistry and mineral composition during viral infection and lysis of cyanobacteria. Amorphous calcium carbonate and aragonite were evident in the lysate, which differed substantially from the lack of calcification in the noninfected culture. We inferred that viral lysis of cyanobacteria can construct an environment of calcification, where carbonate is the dominant inorganic carbon species. Moreover, potential mechanisms involving viruses acting as nucleation sites are also discussed. Altogether, our results expand the role of viruses in mediating sea water carbonate systems and provide new insights in certain global geochemical processes.

Acknowledgments

Authors would like to acknowledge Dr. Dezhang Ren at Shanghai Jiaotong University for his help with the XRD analysis. The authors are also indebted to Dr. Weijia Zhang at the Institute of Deep-sea Science and engineering for her assistance with cyanobacteria identification. Financial support for this research came from “Strategic Priority Research Program” of the Chinese Academy of Science (Grant No. XDB06020000), “National Key Basic Research Program of China” (2015CB755905), and the “Natural Science Foundation of Hainan Province, China” (20164175).

Figure 3: Changes in the solution calcium concentration (a), magnesium concentration (b) and Ma/Ca atomic ratio (c).
Figure 4: Electron microscope images show the formation of ACC nanoparticles in the viral lysate. (a) Nanoparticles with a diameter of approximately 50-200 nm are scattered in the viral lysate. The insert at the bottom right image (b) shows a selected area of the electron diffraction pattern of ACC, revealing only diffuse rings, related to poorly ordered materials (c) Back scattered-electron imaging photomicrographs of host cells infected by virus and mineral particles. (d) Nano-particles with an encrusted structure.
Figure 5: Chemical composition of ACC nanoparticles. (a) STEM images showing ACC nanoparticles. (b, c, d) XEDS maps of Ca, Mg and Si, respectively showing that ACC is composed mainly of Ca. EDS spectra of the nanoparticle shows a small peak of element P (f). However, the P signal from the STEM mapping is not consistent with the nanoparticles (e).

Figure 6: Typical X-ray diffraction patterns collected for each polymorph that formed in this study.
Figure 7: Formation model of the carbonate mineral induced by viral lysis of the cyanobacteria. Although the chemical environment may be favorable for mineral precipitation during photosynthesis, it is unable to facilitate mineralization to the extent that stable CaCO$_3$ precipitates are formed. During the viral lysis of cyanobacteria, there are a few percentages of uninfected cells that require bicarbonate, Mg(OH)$_2$ dissolved to neutralize the dissolution of CO$_2$. Viral lysis of cyanobacteria thus construct a calcification environment where carbonate is the dominant inorganic carbon species. Numerous virus particles available in lysate may coprecipitate with the calcium carbonate.
Table 1 Composition of the artificial seawater (modified F/2 media, final pH was adjust to 8). Regent is purchased from Sinopharm and Sigma-Aldrich.
