Abstract

Inadequate representation of biogeochemical processes in current biogeochemistry models contributes to a large uncertainty in carbon budget quantification. Here, detailed microbial mechanisms were incorporated into a process-based biogeochemistry model, the Terrestrial Ecosystem Model (TEM). Ensemble regional simulations with the new model (MIC-TEM) estimated the carbon budget of the Arctic ecosystems is $76.0 \pm 114.8$ Pg C during the $20^{th}$ century, $-3.1 \pm 61.7$ Pg C under the RCP 2.6 scenario and $94.7 \pm 46$ Pg C under the RCP 8.5 scenario during the $21^{st}$ century. Positive values indicate the regional carbon sink while negative values are source to the atmosphere. Compared to the estimates using a simpler soil decomposition algorithm in TEM, the new model estimated that the Arctic terrestrial ecosystems stored 12 Pg less carbon over the $20^{th}$ century, 19 Pg C and 30 Pg C less under the RCP 8.5 and RCP 2.6 scenarios, respectively, during the $21^{st}$ century. When soil carbon within depths 30 cm, 100 cm and 300 cm was considered as initial carbon in the $21^{st}$ century simulations, the region was estimated to accumulate 65.4, 88.6, and 109.8 Pg C, respectively, under the RCP 8.5 scenario. In contrast, under the RCP 2.6 scenario, the region lost 0.7, 2.2, and 3 Pg C, respectively, to the atmosphere. We conclude that the future regional carbon budget evaluation largely depends on whether or not the adequate microbial activities are represented in earth system models and the sizes of soil carbon considered in model simulations.
1. Introduction

Northern high-latitude soils and permafrost contain more than 1,600 Pg carbon (Tarnocai et al., 2009). Climate over this region has warmed in recent decades (Serreze and Francis, 2006) and the increase is 1.5 to 4.5 times the global mean (Holland and Bitz, 2003). Warming-induced changes in carbon cycling are expected to exert large feedbacks to the global climate system (Davidson and Janssens, 2006; Christensen and Christensen, 2007; Oechel et al., 2000).

Warming is expected to accelerate soil C loss by increasing soil respiration, but increasing nutrient mineralization, thereby stimulating plant net primary production (NPP) (Mack et al., 2004). Thus, the variation of climate may switch the role of the Arctic system between a C sink and a source if soil C loss overtakes NPP (Davidson et al., 2000; Jobbágy and Jackson, 2000). Process-based biogeochemical models such as TEM (Hayes et al., 2014; Raich and Schlesinger, 1992; McGuire et al., 1992; Zhuang et al., 2001, 2002, 2003, 2010, 2013), Biome-BGC (Running and Coughlan, 1988), CASA (Potter et al., 1993), CENTURY (Parton et al., 1994) and Biosphere Energy Transfer Hydrology scheme (BETHY) (Knorr et al., 2000) have been widely used to quantify the response of carbon dynamics to climatic changes (Todd-Brown et al., 2012). An ensemble of process-based model simulations suggests that arctic ecosystems acted as a sink of atmospheric CO$_2$ in recent decades (McGuire et al., 2012; Schimel et al., 2013). However, the response of this sink to increasing levels of atmospheric CO$_2$ and climate change is still uncertain (Todd-Brown et al., 2013). The IPCC 5$^{th}$ report also shows that land carbon storage is the largest source of uncertainty in the global carbon budget quantification (Ciais et al., 2013).
Much of the uncertainty is also due to the inadequate representation of ecosystem processes that determine the exchanges of water, energy and C between land ecosystems and the atmosphere (Wieder et al., 2013), and ignorance of some key biogeochemical mechanisms (Schmidt et al., 2011). For example, heterotrophic respiration ($R_H$) is the primary loss pathway for soil organic carbon (Hanson et al., 2000; Bond-Lamberty and Thomson, 2010), and it generally increases with increasing temperature (Davidson and Janssens, 2006) and moisture levels in well-drained soils (Cook and Orchard, 2008). Moreover, this process is closely related to soil nitrogen mineralization that determines soil N availability and affects gross primary production (Hao et al., 2015). To date, most models treated soil decomposition as a first-order decay process, i.e., CO$_2$ respiration is directly proportional to soil organic carbon. However, it is not clear if these models are robust under changing environmental conditions (Lawrence et al., 2011; Schimel and Weintraub, 2003; Barichivich et al., 2013) since they often ignored the effects of changes in biomass and composition of decomposers, while recent empirical studies have shown that microbial abundance and community play a significant role in soil carbon decomposition (Allison and Martiny, 2008). The control that microbial activity and enzymatic kinetics imposed on soil respiration suggests the need for explicit representation of microbial physiology, enzymatic activity, in addition to the direct effects of soil temperature and soil moisture on heterotrophic respiration (Schimel and Weintraub, 2003). Recent mechanistically-based models explicitly incorporated with the microbial dynamics and enzyme kinetics that catalyze soil C decomposition have produced notably different results and a closer match to contemporary observations (Wieder et al., 2013; Allison et al., 2010) indicating the need for
incorporating these microbial mechanisms into large-scale earth system models to quantify carbon dynamics under future climatic conditions ((Wieder et al., 2013; Allison et al., 2010).

This study advanced a microbe-based biogeochemistry model (MIC-TEM) based on an extant Terrestrial Ecosystem Model (TEM) (Raich and Schlesinger, 1992; McGuire et al., 1992; Zhuang et al., 2001, 2002, 2003, 2010, 2013; Hao et al., 2015). In MIC-TEM, the heterotrophic respiration is not only a function of soil temperature, soil organic matter (SOM) and soil moisture, but also considers the effects of dynamics of microbial biomass and enzyme kinetics (Allison et al., 2010). The verified MIC-TEM was used to quantify the regional carbon dynamics in northern high latitudes (north 45 °N) during the 20th and 21st centuries.

2. Methods

2.1 Overview

Below we first briefly describe how we advanced the MIC-TEM by modifying the soil respiration process in TEM (Zhuang et al., 2003) to better represent carbon dynamics in terrestrial ecosystems. Second, we describe how we parameterized and verified the new model using observed net ecosystem exchange data at representative sites and how simulated net primary productivity (NPP) was evaluated with Moderate Resolution Imaging Spectroradiometer (MODIS) data to demonstrate the reliability of new model at regional scales. Third, we present how we applied the model to the northern high latitudes for the 20th and 21st centuries. Finally, we introduce how we conducted the sensitivity analysis on initial soil carbon input, using gridded observation-based soil carbon data of three soil depths during the 21st century.
2.2 Model description

TEM is a highly aggregated large-scale biogeochemical model that estimates the dynamics of carbon and nitrogen fluxes and pool sizes of plants and soils using spatially referenced information on climate, elevation, soils and vegetation (Raich and Schlesinger, 1992; McGuire et al., 1992; Zhuang et al., 2003, 2010; Melillo et al., 1993). To explicitly consider the effects of microbial dynamics and enzyme kinetics on large-scale carbon dynamics of northern terrestrial ecosystems, we developed MIC-TEM by coupling version 5.0 of TEM (Zhuang et al., 2003, 2010) with a microbial enzyme module (Hao et al., 2015; Allison et al., 2010). Our modification of the TEM improved the representation of the heterotrophic respiration ($R_H$) from a first-order structure to a more detailed structure (Fig. S1).

In TEM, heterotrophic respiration $R_H$ is calculated as a function of soil organic carbon (SOC), soil temperature ($Q_{10}$), soil moisture ($f{\text{(MOIST)}}$), and the gram-specific decomposition constant $K_d$:

$$R_H = K_d \times SOC \times \frac{DT}{Q_{10}} \times f{\text{(MOIST)}}$$

(1)

where $DT$ is soil temperature at top 20 cm. CO$_2$ production from SOC pool is directly proportional to the pool size, and the activity of decomposers only depends on the built-in relationships with soil temperature and moisture (Todd-Brown et al., 2012). Therefore, the changes in microbial community composition or adaption of microbial physiology to new conditions were not represented in TEM. However, current studies indicate that soil C decomposition depends on the activity of biological communities dominated by microbes (Schimel and Weintraub, 2003), implying that the biomass and composition of the decomposer community can’t be ignored (Todd-Brown et al., 2012).
We thus revised the first-order soil C structure in TEM to a second-order structure considering microbial dynamics and enzyme kinetics according to Allison et al. (2010). In MIC-TEM, heterotrophic respiration ($R_H$) is calculated as:

$$R_H = \text{ASSIM} \times (1 - \text{CUE})$$

(2)

Where ASSIM and CUE represent microbial assimilation and carbon use efficiency, respectively. ASSIM is modeled with a Michaelis-Menten function:

$$\text{ASSIM} = V_{\text{max}_\text{uptake}} \times \text{MIC} \times \frac{\text{DOC}}{K_{\text{m}_\text{uptake}} + \text{DOC}}$$

(3)

Where DOC is dissolved organic carbon and $V_{\text{max}_\text{uptake}}$ is the maximum velocity of the reaction and calculated using the Arrhenius equation:

$$V_{\text{max}_\text{uptake}} = V_{\text{max}_\text{uptake}_0} \times e^{\frac{E_{\text{a}_\text{uptake}}}{R \times (\text{temp} + 273)}}$$

(4)

$V_{\text{max}_\text{uptake}_0}$ is the pre-exponential coefficient, $E_{\text{a}_\text{uptake}}$ is the activation energy for the reaction ($\text{Jmol}^{-1}$), $R$ is the gas constant ($8.314 \text{ Jmol}^{-1}\text{K}^{-1}$), and temp is the temperature in Celsius under the reaction occurs.

Besides, $K_{\text{m}_\text{uptake}}$ value is calculated as a linear function of temperature:

$$K_{\text{m}_\text{uptake}} = K_{\text{m}_\text{uptake}_\text{slope}} \times \text{temp} + K_{\text{m}_\text{uptake}_0}$$

(5)

Microbial biomass MIC is modeled as:

$$\frac{d\text{MIC}}{dt} = \text{ASSIM} \times \text{CUE} - \text{DEATH} - \text{EPROD}$$

(6)

Where microbial biomass death (DEATH) and enzyme production (EPROD) are modeled as proportional to microbial biomass with constant rates $r_{\text{death}}$ and $r_{\text{EnzProd}}$:

$$\text{DEATH} = r_{\text{death}} \times \text{MIC}$$

(7)

$$\text{EPROD} = r_{\text{EnzProd}} \times \text{MIC}$$

(8)
Where \( r_{\text{death}} \) and \( r_{\text{EnzProd}} \) are the ratio of microbial death and enzyme production, respectively.

DOC is part of soil organic carbon:

\[
\frac{d\text{DOC}}{dt} = \text{DEATH} \times (1 - \text{MICtoSOC}) + \text{DECAY} + \text{ELOSS} - \text{ASSIM} \quad (9)
\]

where MICtoSOC is carbon input ratio as dead microbial biomass to SOC, representing the fraction of microbial death that flows into SOC, and is set as a constant value according to Allison et al. (2010). SOC dynamics are modeled:

\[
\frac{d\text{SOC}}{dt} = \text{Litterfall} + \text{DEATH} \times \text{MICtoSOC} - \text{DECAY} \quad (10)
\]

Where Litterfall is estimated as a function of vegetation carbon (Zhuang et al., 2010). The enzymatic decay of SOC is calculated as:

\[
\text{DECAY} = \text{V}_{\text{max}} \ast \text{ENZ} \ast \frac{\text{SOC}}{\text{Km} + \text{SOC}} \quad (11)
\]

Where \( V_{\text{max}} \) is the maximum velocity of the reaction and calculated using the Arrhenius equation:

\[
V_{\text{max}} = V_{\text{max},0} \ast e^{\frac{E_a}{R \ast (\text{temp} + 273)}} \quad (12)
\]

The parameters Km and carbon use efficiency (CUE) are temperature sensitive, and calculated as a linear function of temperature between 0 and 50°C:

\[
Km = Km_{\text{slope}} \ast \text{temp} + \text{Km}_0 \quad (13)
\]

\[
\text{CUE} = CUE_{\text{slope}} \ast \text{temp} + \text{CUE}_0 \quad (14)
\]

Where CUEslope and CUE0 are parameters for calculating CUE, and Kmslope and Km0 are parameters for calculating Km. The values of CUEslope, CUE0, Kmslope, and Km0 were derived from Allison et al. (2010).

ELOSS is also a first-order process, representing the loss of enzyme:

\[
\text{ELOSS} = r_{\text{enzloss}} \ast \text{ENZ} \quad (15)
\]
Where $r_{\text{enzloss}}$ is the ratio of enzyme loss. Enzyme pool (ENZ) is modeled:

$$\frac{d\text{ENZ}}{dt} = \text{EPROD} - \text{ELOSS} \quad (16)$$

Heterotrophic respiration ($R_H$) is an indispensable component of soil respiration (Bond-Lamberty and Thomson, 2010), and closely coupled with soil nitrogen (N) mineralization that determines soil N availability, affecting gross primary production (GPP).

\[2.3 \text{ Model parameterization and validation}\]

The variables and parameters of these microbial dynamics and their impacts on soil C decomposition were detailed in Allison et al. (2010) (Table 1). Here we parameterized MIC-TEM for representative ecosystem types in northern high latitudes based on monthly net ecosystem productivity (NEP, gC m$^{-2}$ mon$^{-1}$) measurements from AmeriFlux network (Davidson et al., 2000) (Table S1). The results for model parameterization was presented in Fig. S2.

Another set of level 4 gap-filled NEP data was used for model validation at site level (Table S2). The site-level monthly climate data of air temperature ($\degree$C), precipitation (mm) and cloudiness (%) were used to drive the model. Gridded MODIS NPP data from 2001 to 2010 were used to evaluate regional NPP simulation. The MODIS NPP data was developed by the MOD17 MODIS project. The product name is Net Primary Production Yearly L4 Global 1 km. The critical parameter used in MOD17 algorithm is conversion efficiency parameter $\varepsilon$. More information about the MODIS NPP product can be found at [https://neo.sci.gsfc.nasa.gov/view.php?datasetId=MOD17A2_M_PSN](https://neo.sci.gsfc.nasa.gov/view.php?datasetId=MOD17A2_M_PSN).

In TEM, NPP is calculated as:
NPP = GPP - RA \quad (17)

Where GPP is gross primary production, and RA is autotrophic respiration.

GPP = C_{max} \cdot f(PAR) \cdot f(moist) \cdot f(foliage) \cdot f(T) \cdot f(CO_2) \cdot f(NA) \quad (18)

For detailed GPP and RA calculations, see Zhuang et al. (2003). The parameterization was conducted with a global optimization algorithm SCE-UA (Shuffled complex evolution) (Duan et al., 1994) to minimize the difference between the monthly simulated and measured NEE at these sites (Fig. S2). The cost function of the minimization is:

$$\text{Obj} = \sum_{i=1}^{k} (\text{NEP}_{\text{obs},i} - \text{NEP}_{\text{sim},i})^2 \quad (19)$$

Where NEP_{obs,i} and NEP_{sim,i} are the observed and simulated NEP, respectively. k is the number of data pairs for comparison. Other parameters used in MIC-TEM were default values from TEM 5.0 (Zhuang et al., 2003, 2010). The optimized parameters were used for model validation and regional extrapolations.

2.4 Regional simulations

Two sets of regional simulations for the 20th century using MIC-TEM and TEM at a spatial resolution of 0.5° latitude × 0.5° longitude were conducted. Gridded forcing data of monthly air temperature, precipitation, and cloudiness were used, along with other ancillary inputs including historical atmospheric CO_2 concentrations, soil texture, elevation, and potential natural vegetation. Climatic inputs vary over time and space, whereas soil texture, elevation, and land cover data are assumed to remain unchanged throughout the 20th century, which only vary spatially. The transient climate data during the 20th century was organized from the Climatic
Research Unit (CRU TS3.1) from the University of East Anglia (Harris et al., 2014). The spatial-explicit data include potential natural vegetation (Melillo et al., 1993), soil texture (Zhuang et al., 2003) and elevation (Zhuang et al., 2015).

Similarly, two sets of simulations were conducted driven with two contrasting climate change scenarios (RCP 2.6 and RCP 8.5) over the 21st century. The future climate change scenarios were derived from the HadGEM2-ES model, which is a member of CMIP5 project (https://esgf-node.llnl.gov/search/cmip5/). The future atmospheric CO$_2$ concentrations and climate forcing from each of the two climate change scenarios were used. The simulated NPP, $R_H$ and NEP by both models (TEM 5.0 and MIC-TEM) were analyzed. The positive NEP represents a CO$_2$ sink from the atmosphere to terrestrial ecosystems, while a negative value represents a source of CO$_2$ from terrestrial ecosystems to the atmosphere.

Besides, in order to test the parameter uncertainty in our model, we conducted the regional simulations with 50 sets of parameters for both historical and future studies. The 50 sets of parameters were obtained according to the method in Tang and Zhuang (2008). The upper and lower bounds of the regional estimations were generated based on these simulations.

2.5 Sensitivity to initial soil carbon input

Future carbon dynamics can be affected by varying initial soil carbon amount. In the standard simulation of TEM, the initial soil carbon amount for transient simulations was obtained from equilibrium and spin-up periods directly for each grid cell in the region. To test the sensitivity to the initial soil carbon amount in transient simulations for the 21st century, we used empirical soil organic carbon data extracted from the Northern Circumpolar Soil Carbon Database (NCSCD)
(Tarnocai et al., 2009), as the initial soil carbon amount. The $0.5^\circ \times 0.5^\circ$ soil carbon data products for three different depths of 30cm, 100cm and 300cm were used. The sensitivity test was conducted for transient simulations under the RCP 2.6 and RCP 8.5 scenarios. To avoid the instability of C-N ratio caused by replacing the initial soil carbon pool with observed data at the beginning of transient period, initial soil nitrogen values were also generated based on the soil carbon data and corresponding C-N ratio map for transient simulations (Zhuang et al., 2003; Raich and Schlesinger, 1992).

3. Results

3.1 Model verification at site and regional levels

With the optimized parameters, MIC-TEM reproduces the carbon dynamics well for alpine tundra, boreal forest, temperate coniferous forest, temperate deciduous forest, grasslands and wet tundra with $R^2$ ranging from 0.70 for Ivotuk to 0.94 for Bartlett Experimental Forest (Fig. S3, table S3). In general, model performs better for forest ecosystems than for tundra ecosystems. The temporal NPP from 2001 to 2010 simulated by MIC-TEM and TEM were compared with MODIS NPP data (Fig. S4). Pearson correlation coefficients are 0.52 (MIC-TEM and MODIS) and 0.34 (TEM and MODIS). NPP simulated by MIC-TEM showed higher spatial correlation coefficients with MODIS data than TEM (Fig. S5). By considering more detailed microbial activities, the heterotrophic respiration is more adequately simulated using the MIC-TEM. The simulated differences in soil decomposition result in different levels of soil available nitrogen, which influences the nitrogen uptake by plants, the rate of photosynthesis and NPP. The spatial
The correlation coefficient between NPP simulated by MIC-TEM and MODIS is close to 1 in most study areas, suggesting the reliability of MIC-TEM at the regional scale.

### 3.2 Regional carbon dynamics during the 20th century

The equifinality of the parameters in MIC-TEM was considered in our ensemble regional simulations to measure the parameter uncertainty (Tang and Zhuang, 2008). Here and below, the ensemble means and the inter-simulation standard deviations are shown for uncertainty measure, unless specified as others. These ensemble simulations indicated that the northern high latitudes act from a carbon source of 38.9 PgC to a carbon sink of 190.8 PgC by different ensemble members, with the mean of 64.2±21.4 Pg at the end of 20th century while the simulation with the optimized parameters estimates a regional carbon sink of 77.6 Pg with the interannual standard deviation of 0.21 PgC yr\(^{-1}\) during the 20th century (Fig 1). Simulated regional NEP with optimized parameters using TEM and MIC-TEM showed an increasing trend throughout the 20th century except a slight decrease during the 1960s (Fig. 2). The Spatial distributions of NEP simulated by MIC-TEM for different periods in 20th century also show the increasing trend (Fig 3). Positive values of NEP represent sinks of CO\(_2\) into terrestrial ecosystems, while negative values represent sources of CO\(_2\) to the atmosphere. From 1900 onwards, both models estimated a regional carbon sink during the 20th century. With optimized parameters, TEM estimated higher NPP and \(R_H\) at 0.6 PgC yr\(^{-1}\) and 0.3 PgC yr\(^{-1}\) than MIC-TEM, respectively, at the end of the 20th century (Fig. 2). The MIC-TEM estimated a carbon sink increase from 0.64 to 0.83 PgCyr\(^{-1}\) during the century while the estimated increase by TEM was much higher (0.28 PgCyr\(^{-1}\)) (Fig. 2). At the end of the century, MIC-TEM estimated NEP reached 1.0 PgCyr\(^{-1}\) in comparison with
TEM estimates of 0.3 PgC yr\(^{-1}\). TEM estimated NPP and R\(_H\) are 0.5 PgC yr\(^{-1}\) and 0.3 PgC yr\(^{-1}\) higher, respectively. As a result, TEM estimated that the region accumulated 11.4 Pg more carbon than MIC-TEM. Boreal forests are a major carbon sink at 0.55 and 0.63 PgC yr\(^{-1}\) estimated by MIC-TEM and TEM, respectively. Alpine tundra contributes the least sink. Overall, TEM overestimated the sink by 12.5\% in comparison to MIC-TEM for forest ecosystems and 16.7\% for grasslands. For wet tundra and alpine tundra, TEM overestimated about 20\% and 33\% in comparison with MIC-TEM, respectively (Table 2).

### 3.3 Regional carbon dynamics during the 21\textsuperscript{st} century

Regional annual NPP and R\(_H\) increases under the RCP 8.5 scenario according to simulations with both models (Fig. 4). With optimized parameters, MIC-TEM estimated NPP increases from 9.2 in the 2000s to 13.2 PgC yr\(^{-1}\) in the 2090s, while TEM predicted NPP is 2.0 PgC yr\(^{-1}\) higher in the 2000s and 0.3 PgC yr\(^{-1}\) higher in the 2090s (Fig. 4). Similarly, TEM also overestimated R\(_H\) by 1.7 PgC yr\(^{-1}\) in the 2000s and 0.25 PgC yr\(^{-1}\) higher in the 2090s, respectively (Fig. 4). As a result, the regional sink increases from 0.53 PgC yr\(^{-1}\) in the 2000s, 1.4 PgC yr\(^{-1}\) in the 2070s, then decreases to 1.1 PgC yr\(^{-1}\) in the 2090s estimated by MIC-TEM (Fig. 4). Given the uncertainty in parameters, MIC-TEM predicted the region acts as a carbon sink ranging from 48.7 to 140.7 Pg, with the mean of 71.7±26.6 Pg at the end of 21\textsuperscript{st} century, while the simulation with optimized parameters estimates a regional carbon source of 79.5 Pg with the interannual standard deviation of 0.37 PgC yr\(^{-1}\) during the 21\textsuperscript{st} century (Fig 4). TEM predicted a similar trend for NEP, which overestimated the carbon sink with magnitude of 19.2 Pg compared with the simulation by MIC-TEM with optimized parameters. Under the RCP 2.6 scenario (Fig. 4), the increase of NPP and
\( R_H \) is smaller from 2000 to 2100 compared to the simulation under the RCP 8.5. MIC-TEM predicted that NPP increases from 9.1 to 10.9 PgCyr\(^{-1}\), TEM estimated 1.6 PgCyr\(^{-1}\) higher at the beginning and 0.9 PgCyr\(^{-1}\) higher in the end of the 21\(^{st}\) century (Fig. 4). Consequently, MIC-TEM predicted NEP fluctuates between sinks and sources during the century, with a neutral before 2070, and a source between -0.2 - -0.3 Pg C yr\(^{-1}\) after the 2070s. As a result, the region acts as a carbon source of 1.6 Pg C with the interannual standard deviation of 0.24 PgC yr\(^{-1}\) estimated with MIC-TEM and a sink of 27.6 Pg C with the interannual standard deviation of 0.2 PgC yr\(^{-1}\) estimated with TEM during the century (Fig. 4). When considering the uncertainty source of parameters, MIC-TEM predicted the region acts from a carbon source of 64.8 Pg C to a carbon sink of 58.6 Pg C during the century with the mean of -3.3±20.3 Pg at the end of 21\(^{st}\) century (Fig 4).

### 3.4 Model sensitivity to initial soil carbon

Under the RCP 2.6, without replacing the initial soil carbon with inventory-based estimates\(^1\) in model simulations, TEM estimated that the regional soil organic carbon (SOC) is 604.2 Pg C and accumulates 12.1 Pg C during the 21\(^{st}\) century. When using estimated soil carbon\(^1\) within depths of 30cm, 100cm and 300cm as initial pools in simulations, TEM predicted that regional SOC is 429.5, 689.3 and 1003.4 Pg C in 2000, and increases by 9.9, 16.0 and 22.8 Pg C at the end of the 21\(^{st}\) century, and the regional cumulative carbon sink is 20.4, 34.0, and 48.1 Pg C, respectively during the century. In contrast, using the same inventory-based SOC estimates, MIC-TEM projected that the region acts from a cumulative carbon sink to a source at 0.7, 2.2, and 3.0 Pg C,
respectively. Under the RCP 8.5, both models predicted that the region acts as a carbon sink, regardless of the magnitudes of initial soil carbon pools used, with TEM projected sink of 71.7, 120, and 155.6 Pg C and a much smaller cumulative sink of 65.4, 88.6, and 109.8 Pg C estimated with MIC-TEM, respectively (Table 3).

4. Discussion

During the last few decades, a greening accompanying warming and rising atmospheric CO₂ in the northern high latitudes (>45° N) has been documented (McGuire et al., 1995; McGuire and Hbbie, 1997; Chapin and Starfield, 1997; Stow et al., 2004; Callaghan et al., 2005; Tape et al., 2006). The large stocks of carbon contained in the region (Tarnocai et al., 2009) are particularly vulnerable to climate change (Schuur et al., 2008; McGuire et al., 2009). To date, the degree to which the ecosystems may serve as a source or a sink of C in the future are still uncertain (McGuire et al., 2009; Wieder et al., 2013). Therefore, accurate models are essential for predicting carbon–climate feedbacks in the future (Todd-Brown et al., 2013). Our regional simulations indicate the region is currently a carbon sink, which is consistent with many previous studies (White et al., 2000; Houghton et al., 2007), and this sink will grow under the RCP 8.5 scenario, but shift to a carbon source under the RCP 2.6 scenario by 2100. MIC-TEM shows a higher correlation between NPP and soil temperature (R=0.91) than TEM (R=0.82), suggesting that MIC-TEM is more sensitive to environmental changes (Table S4).

Our regional estimates of carbon fluxes by MIC-TEM are within the uncertainty range from other existing studies. For instance, Zhuang et al. (2003) estimated the region as a sink of 0.9 PgCyr⁻¹ in extratropical ecosystems for the 1990s, which is similar to our estimation of 0.83 PgCyr⁻¹ by MIC-TEM. White et al. (2000) estimated that, during the 1990s, regional NEP above
50 °N region is 0.46 PgCyr\(^{-1}\) while Qian et al. (2010) estimated that NEP increased from 0 to 0.3 PgCyr\(^{-1}\) for the high-latitude region above 60 °N during last century, and reached 0.25 PgCyr\(^{-1}\) during the 1990s. White et al. (2000) predicted that, from 1850 to 2100, the region accumulated 134 PgC in terrestrial ecosystems, in comparison with our estimates of 77.6 PgC with MIC-TEM and 89 PgC with TEM. Our projection of a weakening sink during the second half of the 21\(^{st}\) century is consistent with previous model studies (Schaphoff et al., 2013). Our predicted trend of NEP is very similar to the finding of White et al. (2000), indicating that NEP increases from 0.46 PgCyr\(^{-1}\) in the 2000s and reaches 1.5 PgCyr\(^{-1}\) in the 2070s, then decreases to 0.6 PgCyr\(^{-1}\) in the 2090s.

The MIC-TEM simulated NEP generally agrees with the observations. However, model simulations still deviate from the observed data, especially for tundra ecosystems. The deviation may be due to the uncertainty or errors in the observed data, which do not well constrain the model parameters. Uncertain driving data such as temperature and precipitation are also a source of uncertainty for transient simulations. In addition, we assumed that vegetation will not change during the transient simulation. However, over the past few decades in the northern high latitudes, temperature increases have led to vegetation changes (Hansen et al., 2006), including latitudinal treeline advance (Lloyd et al., 2005) and increasing shrub density (Sturm et al., 2001). Vegetation can shift from one type to another because of competition for light, N and water (White et al., 2000). For example, needleleaved trees tend to replace tundra gradually in response to warming. In some areas, forests even moved several hundreds of kilometers within 100 years (Gear and Huntley, 1991). The vegetation changes will affect carbon cycling in these ecosystems. In addition, we have not yet considered the effects of management of agriculture lands (Cole et al.,
1997), but Zhuang et al. (2003) showed that the changes in agricultural land use in northern high latitudes have been small.

The largest limitation to this study is that we have not explicitly considered the fire effects. Warming in the northern high latitudes could favor fire in its frequency, intensity, seasonality and extent (Kasischke and Turetsky, 2006; Johnstone and Kasischke, 2005; Soja et al., 2007; Randerson et al., 2006; Bond-Lamberty et al., 2007). Fire has profound effects on northern forest ecosystems, altering the N cycle and water and energy exchanges between the atmosphere and ecosystems. Increase in wildfires will destroy most of above-ground biomass and consume organic soils, resulting in less carbon uptake by vegetation (Harden et al., 2000), leading to a net release of carbon in a short term. However, a suite of biophysical mechanisms of ecosystems including post-fire increase in the surface albedo and rates of biomass accumulation may in turn, exert a negative feedback to climate warming (Amiro et al., 2006; Goetz et al., 2007), further influence the carbon exchanges between ecosystems and the atmosphere.

Moreover, carbon uptake in land ecosystems depends on new plant growth, which connects tightly with the availability of nutrients such as mineral nitrogen. Recent studies have shown that when soil nitrogen is in short supply, most terrestrial plants would form symbiosis relationships with fungi; hyphae provides nitrogen to plants, in return, plants provide sugar to fungi (Hobbie and Hobbie, 2008, 2006; Schimel and Hättenschwiler, 2007). This symbiosis relationship has not been considered in our current modeling, which may lead to a large uncertainty in our quantification of carbon and nitrogen dynamics.
Shift in microbial community structure was not considered in our model, which could affect the temperature sensitivity of heterotrophic respiration (Stone et al., 2012). Michaelis-Menten constant (K_m) could also adapt to climate warming, and it may increase more significantly with increasing temperature in cold-adapted enzymes than in warm-adapted enzymes (German et al., 2012; Somero et al., 2004; Dong and Somero, 2009). Carbon use efficiency (CUE) is also a controversial parameter in our model. Empirical studies in soils suggest that microbial CUE declines by at least 0.009 °C^{-1} (Steinweg et al., 2008), while other studies find that CUE is invariant with temperature (López-Urrutia and Morán, 2007). Another key microbial trait lacking in our modeling is microbial dormancy (He et al., 2015). Dormancy is a common, bet-hedging strategy used by microorganisms when environmental conditions limit their growth and reproduction (Lennon and Jones, 2011). Microorganisms in dormancy are not able to drive biogeochemical processes such as soil CO_2 production, and therefore, only active microorganisms should be involved in utilizing substrates in soils (Blagodatskaya and Kuzyakov, 2013). Many studies have indicated that soil respiration responses to environmental conditions are more closely associated with the active portion of microbial biomass than total microbial biomass (Hagerty et al., 2014; Schimel and Schaeffer, 2012; Steinweg et al., 2013). Thus, the ignorance of microbial dormancy could fail to distinguish microbes with different physiological states, introducing uncertainties to our carbon estimation.

5. Conclusions

This study used a more detailed microbial biogeochemistry model to investigate the carbon dynamics in the region for the past and this century. Regional simulations using MIC-TEM indicated that, over the 20th century, the region is a sink of 77.6 Pg. This sink could reach to 79.5
Pg under the RCP 8.5 scenario or shift to a carbon source of 1.6 Pg under the RCP 2.6 scenario during 21st century. On the other hand, traditional TEM overestimated the carbon sink under the RCP 8.5 scenario with magnitude of 19.2 Pg than MIC-TEM, and predicted this region acting as carbon sink with magnitude of 27.6 Pg under the RCP 2.6 scenario during 21st century. Using recent soil carbon stock data as initial soil carbon in model simulations, the region was estimated to shift from a carbon sink to a source, with total carbon release at 0.7-3 Pg by 2100 depending on initial soil carbon pools at different soil depths under the RCP 2.6 scenario. In contrast, the region acts as a carbon sink at 55.4-99.8 Pg C in the 21st century under RCP 8.5 scenario. Without considering more detailed microbial processes, models estimated that the region acts as a carbon sink under both scenarios. Under the RCP 2.6 scenario, the cumulative sink ranges from 9.9 to 22.8 Pg C. Under the RCP 8.5 scenario, the cumulative sink is even larger at 71.7-155.6 Pg C. This study indicated that more detailed microbial physiology-based biogeochemistry models estimate carbon dynamics very differently from using a relatively simple microbial decomposition-based model. The comparison with satellite products or other estimates for the 20th century suggests that the more detailed microbial decomposition shall be considered to adequately quantify C dynamics in northern high latitudes.

Acknowledgments

This research was supported by a NSF project (IIS-1027955), a DOE project (DE-SC0008092), and a NASA LCLUC project (NNX09AI26G) to Q. Z. We acknowledge the Rosen High
Performance Computing Center at Purdue for computing support. We thank the National Snow and Ice Data center for providing Global Monthly EASE-Grid Snow Water Equivalent data, National Oceanic and Atmospheric Administration for North American Regional Reanalysis (NARR), and Hugelius and his group by making available pan-Arctic permafrost soil C maps. We also acknowledge the World Climate Research Programme’s Working Group on Coupled Modeling Intercomparison Project CMIP5, and we thank the climate modeling groups for producing and making available their model output. The data presented in this paper can be accessed through our research website (http://www.eaps.purdue.edu/ebdl/)
