Dear Prof. Michael Bahn,

Please find attached a revised version of the manuscript, “Carbon Dioxide and Methane Emissions from Red Sea Mangrove Sediments,” now entitled “Carbon Dioxide and Methane Fluxes at the Air-Sea Interface of Red Sea Mangroves” for publication reconsideration in Biogeosciences.

We would like to sincerely thank the reviewers for their suggestions, which have significantly improved the manuscript. We have attached a detailed response to the reviewers’ comments, noting all changes made to reflect their recommendations. We believe that these revisions have greatly improved the manuscript’s content and readability and hope you find this draft acceptable for publication in its present form.

Yours sincerely,

Sea and co-authors
We wish to sincerely thank reviewer #1 for his/her comments and suggestions that were very helpful in improving and clarifying the MS.

Anonymous Referee #1:

Detailed comments

1. I focus here only on the methodology aspects since in my opinion the approach does not measure CO2 emission rates correctly, and the d13C data are similarly not representative. These concerns invalidate the discussion and conclusions on CO2 fluxes and sources of CO2. The authors used 2 different experimental setups to perform their incubations. In both cases, CO2 fluxes are derived from an increase in the partial pressure of CO2 in the water column overlying the sediment in a sediment core; either by directly measuring pCO2 in the water (described in section 2.3.1) or by measuring pCO2 in the headspace above the water column in a sediment-water-headspace incubation (described in section 2.3.2). Both approaches assume that all CO2 produced in – and released from – the sediment accumulates as CO2 in the overlying water, and equilibrates with CO2 in the headspace (for the 2nd approach), but ignores the fact that dissolved CO2 will rapidly equilibrate with dissolved HCO3- and CO32- (see for example Schulz et al. Marine Chemistry 100: 53-65 for a discussion on the kinetics of the inorganic carbon equilibration). What should be determined is the change in the total DIC concentration, rather than only looking at CO2.

Reviewer one provides thought-provoking insights on carbonate chemistry in seawater, with specific concerns focusing on the need to consider DIC fractionation in order to properly assess the fluxes of DIC between sediment and water due to photosynthesis, respiration and numerous Red-Ox processes.

We absolutely agree with the comment of reviewer 1, however, our intent is to measure the fluxes at the air-sea interface, i.e. quantify the net GHG emissions to the atmosphere. It seems that our language in several places made our intent more ambiguous than realized. Air-sea equilibrators have been used in numerous studies to assess net CO2 emissions by marine ecosystems, such as in Borges et al., 2003 in inundated mangrove swamps.

In the new version of the MS, we make our scientific goals and interests more transparent through numerous, related changes:

Title

The title has been changed to “Carbon Dioxide and Methane Fluxes at the Air-Sea Interface of Red Sea Mangroves” to reflect this goal.

Introduction

We introduce the idea of measuring emissions in different ways in lines 74-78:

“Previous studies on GHG emission rates either focus on the soil-atmosphere interface, highlighting substantial flux ranges with mangroves reported to act as negligible (Alongi, 2005) to considerable sources (Livesley and Andrusiak, 2012; Chen et al., 2016), or examine net fluxes at the air-sea interface, with few studies in arid systems.”
We clarify our goals in lines 87-90:

“Here we report air-sea emission rates of CO$_2$ and CH$_4$, along with their carbon isotopic composition, from incubations of inundated mangrove sediments cores along the Saudi coast of the Red Sea. We assess the relative role of these two gases in supporting total GHG emissions as well as their fluctuations along the day-night cycle.”

Discussion

The discussion has now been divided into 2 subsections, the first of which addresses the limitations of our methodology and subsequent comparison abilities (Lines 315-339):

4.1 Greenhouse Gas Fluxes

“While this study provides new insights on GHG fluxes from arid mangroves, the methods used here solely measure the air-sea fluxes of dissolved gases. If CO$_2$ is produced from underlying sediments, it enters the water column and becomes a part of the carbonate system, with possibility of conversion to bicarbonate (HCO$_3^-$) and carbonate (CO$_3^{2-}$) ions; these dominating species represent over 99% of the dissolved inorganic carbon (DIC) under current atmospheric and oceanic conditions (Zeebe and Wolf-Gladrow, 2001). Therefore, the air-sea equilibration methods used in this study do not measure DIC fluxes, but only the fluxes of the dissolved CO$_2$-component of this larger system.

Frankignoulle and Borges (2001) show that CO$_2$ can be measured either directly (using equilibrator techniques and spectroscopy or chromatography) or indirectly (by making calculations based on pH, total alkalinity, and DIC). The methodology presented in this study represents the former, utilizing an air-sea equilibrator connected to a CRDS to measure GHG fluxes at the air-sea interface. Research conducted by Borges et al. (2003) utilizes the indirect approach, using pH and total alkalinity measurements in Papua New Guinea to calculate DIC and CO$_2$(dis) (for a computational discussion see Frankignoulle and Borges, 2001). Both methods measure at the air-sea interface (Table Two) but are not directly comparable, as a full determination of the carbonate system was not carried out in the present study. Similarly, studies using equilibrator techniques that measure the dissolved CO$_2$ fraction of seawater to the atmosphere are influenced by the seawater carbonate system and further steps of isotopic fraction (discussed below), and are therefore not directly comparable to those studies which measure GHG fluxes from exposed mangrove sediments to the atmosphere (Table Two).”

We delete the possibility of closing the carbon budget with our study (lines 31-33 and 303-309) and add the possibility of future studies to do so (lines 299-305):

“Reported organic carbon burial rates of Red Sea mangroves of 3.42 mmol C m$^{-2}$ d$^{-1}$ (Almahasheer et al. 2017) are 10 times larger than the combined average CO$_2$ and CH$_4$ emission rates reported here (0.37 mmol C m$^{-2}$ d$^{-1}$), suggesting that these mangrove sediments could act as net atmospheric carbon sinks; however, significant annual alkalinity and DIC exports have been identified from mangroves as well (Sippo et al., 2016), necessitating future studies which measure these exports to neighboring habitats in order to close the carbon budget and determine the role of Red Sea mangroves in potential climate change mitigation.”
Conclusion

Two concluding paragraphs have been added, tying together our thoughts and final remarks (lines 401-423). The second paragraph again addresses the limitations of our study (lines 415-423):

“Methods presented in this study include the use of an air-sea equilibrator connected to a CRDS to measure GHG fluxes at the air-sea interface, measuring the dissolved CO$_2$ component of the larger seawater carbonate system. This methodology is one of many used to measure GHG flux rates; establishing a unified sampling technique at both the soil-atmosphere and air-seawater interface will aid future researchers in determining total carbon budgets and accurately informing policymakers of their findings. In combination with consideration of isotope effects, a full determination of the carbonate system will be beneficial in future studies to further resolve GHG fluxes in arid mangroves, allowing us to better ascertain the role of these forests in global carbon budgets.”

Table Two

References in Table Two have been added, deleted, and reorganized to better reflect related studies:

Deleted
Kristensen et al., 2008a
Alongi, 2014
Chuang et al., 2015

Added
Borges et al., 2003
Bouillon et al., 2003
Bouillon et al., 2007a
Bouillon et al., 2007b
Bouillon et al., 2007c
Call et al., 2015
Ho et al., 2014
Jacotot et al. 2018
Rosentreter et al. 2018a
Rosentreter et al. 2018b

Changes have also been made to Table Two to distinguish between measurements made at the [1] soil-atmosphere interface, [2] air-sea interface with DIC calculation methods, and [3] air-sea interface with equilibration methods.

In addition to these alterations, smaller word choice changes were made throughout the document to clarify our intent:

Line 77: “examine net fluxes at the air-sea interface”
We measured CO$_2$ and CH$_4$ air-sea fluxes

Inundated mangrove sediments

2. Since there is isotope fractionation in the inorganic C system, with CO$_2$ being substantially depleted in 13C relative to bicarbonate, the changes in d13C in CO$_2$ in the headspace are not directly linked to the CO$_2$ produced in the sediment by respiration, but are transformed during equilibration in the water column overlying the sediment, and there is an additional fractionation step between aqueous (dissolved) and gaseous CO$_2$ (in the headspace). Hence, the Keeling plot approach will not provide a reliable way of determining the source of CO$_2$ produced – both the concentration and the d13C data determined in the authors’ approach are not relevant; it is the total DIC concentration and d13C of the total DIC pool (or rather, DIC + CO$_2$ in headspace) that should have been measured.

We concur with Reviewer #1’s thoughts and consequently discuss the limitation of our method, acknowledging that our resulting d$^{13}$C signals in the air phase comes after several steps of isotopic segregation. This is done in the following places:

Abstract

We make conditional conconclusions due to the limitations of our methods (Lines 24-29):

"Based on the isotopic composition of the CO$_2$ and CH$_4$ produced, we identified potential origins of the organic matter that support GHG emissions. In all but one mangrove stand, GHG emissions appear to be supported by organic matter from mixed sources, potentially reducing CO$_2$ fluxes and instead enhancing CH$_4$ production, a finding that highlights the importance of determining the origin of organic matter in GHG emissions"

Discussion

The discussion has now been divided into 2 subsections, the second of which addresses isotopic segregation and its influence on our results (Lines 343-363):

4.2 Isotopic Composition of Emitted Gases

"There were no relationships between GHG fluxes and sediment properties, such as chlorophyll $a$, nitrogen density, and organic carbon density, suggesting that other factors have greater influence on GHG flux rates in this region. Since mangroves can receive large contributions of organic carbon from other sources (Newell et al., 1995), such as algal mats, seagrass and seaweed, examination of the isotopic composition of emitted carbon provides insights into the origin of the organic carbon supporting GHG fluxes in mangrove sediments; however, it should be noted that $\delta^{13}$C values reported in this study occur after several steps of isotopic fractionation and may therefore influence results. Isotope effects can cause an unequal distribution of isotopes between DIC components; for example as CO$_2$ is produced from mangrove sediments and becomes part of the carbonate system (likely forming HCO$_3^-$ after equilibration), molecules containing the heavier carbon isotope—with a higher activation energy—will typically react more slowly (Zeebe and Wolf-Gladrow, 2001), promoting a higher concentration of the heavy isotope in unreacted CO$_2$ and a relative depletion of this heavier isotope in resulting HCO$_3^-$.\"
Similarly, this preferential incorporation and movement of molecules containing lighter isotopes can affect resulting carbon isotope ratios after air-sea equilibration (with depletion of lighter isotopes in seawater as a result of fractionation). CO₂ measured in this study is subject to these processes and may not reflect the isotopic ratios of carbon originally emitted; rather, the signatures measured in this study should be seen as a proxy which reflects isotopic ratios of air-sea discrimination and biological processing (decomposition, respiration, and photosynthesis) resulting after carbon isotope fractionation. Interpretation of results is therefore subject to this limitation.”

We also make conditional conclusions in this section due to the limitations of our methods:

Lines 380-385: “Moreover, the mean isotopic signature of the CH₄ produced in mangrove sediments (δ¹³C-CH₄ = -80.6 ‰) tentatively confirms its biogenic origin”

Lines 387-389: “The lowest δ¹³C-CH₄ was detected in S3, coinciding with the lowest δ¹³C-CO₂ value, suggesting that the organic matter being decomposed by methanogens likely came from mangrove tissues as well”

Lines 392-397: “Organic matter with lighter isotopic composition could enhance CO₂ emissions, whereas organic matter with heavier isotopic composition could enhance CH₄ emissions (Fig. 5), possibly suggesting a different preferential use of organic matter by different microbial groups in mangrove sediments. Future studies exploring this idea with further considerations of carbon isotope fractionation would help solidify the role of the origin of organic carbon stored in mangrove sediments on their GHG emissions.”

Lines 406-409: “This study also highlights the importance of determining the source of organic matter in GHG flux studies, as emissions appear to be supported by organic matter from mixed sources in the majority of studied mangroves, potentially enhancing CH₄ production over CO₂ fluxes in this system.”

We would also like to thank reviewer #2 for his/her comments and suggestions that were very helpful in improving and clarifying the MS.

Anonymous Referee #2:

1. Line 134 For cores S1 and S1, you need to factor in the equilibration time of the membrane equilibrator as this would affect your rate calculations (Webb 2016 L&O). By not accounting for equilibration time the flux estimates would underestimate emission rates.
We recognize that air-water equilibrators exhibit a delay in the measured response of gas concentration and that, for some applications requiring exact CO₂ concentrations at a given time, there is a need to deconvolve the CO₂ or CH₄ time series. However, our study focused on rates, calculated as the slope during a phase in which we observed a linear increase or decrease of gases for periods of 20 to 30 minutes. Convolution of the time series due to lag would not affect those rates.

2. Line 46 Should be 12%
   Line 46 (now line 49) was changed from 13% to 12%.

3. Line 198: Using the data in Table 1, I calculate a mean CO₂ flux of 1358 ± 1195 umol m⁻² day⁻¹.
   It is possible that reviewer two calculated a mean CO₂ flux of 1358 umol m⁻² day⁻¹ if he or she accidentally plugged in +3452 for station 1 instead of -3452 for station 1. This would create a mean CO₂ flux of 1358 instead of 372.

4. Line 201: You do not include the negative flux numbers in the reported range. I find the variability of the source/sink behaviour of CO₂ at the different sites to be one of the most interesting findings of the paper and there is limited speculation or use of the literature to suggest why that may be. I would suggest a deeper interpretation is necessary. Factors including the disturbance if sediments during coring may be particularly relevant as crab burrows would no doubt be affected and coring through mangrove roots may disturb the entire sediment matrix.
   We report the range of CO₂ fluxes observed to be -3452 to 7500 μmol CO₂ m⁻² d⁻¹; it is possible that reviewer two did not see the negative sign associated with -3452 as the negative symbol appears on line 200 while the number 3452 appears on line 201. We moved the negative sign down to the next line to make this more clear (now line 224). We wholeheartedly agree with the reviewer’s thoughts that the high degree of flux variability is an interesting finding and have subsequently added our thoughts on this matter:

   Lines 270-276: “Additionally it is possible that differences in flux rates may exist as a result of sediment disturbance from the coring process. The effects of mangrove pneumatophores and possible bioturbation from infaunal species such as burrowing crabs were not considered here yet could pose another possible source of variation in results as the presence of these structures influences oxygenation of sediment and pore water exchange, identified as driving factors in varying CO₂ levels (Call et al., 2014; Rosentreter et al., 2018). These factors likely affect relevant redox processes and would therefore be useful to quantify in future studies.”

5. Line 202 It was 5 out of the 7 sites where daytime uptake and night time production was seen.
   Line 202 was originally written to denote an overall observation, as the majority of sites absorbed CO₂ during the day and emitted at night. We appreciate the reviewer’s attention to detail and have changed line 202 (now 226-227) to “Mangrove sediments absorbed CO₂ during daytime and emitted CO₂ during night time at 5 out of 7 stations.”

6. Line 203 the units should be umol CO₂ m⁻² hr⁻¹
   We apologize for this error; units were corrected on line 203 (now 227).
Averages and standard errors would be useful in Table 2. As noted above, we feel that one of the more interesting findings in our study (and similar studies) is the wide variability in reported flux values. We choose to keep flux ranges in Table 2 and add averages (±SE) in the text as suggested (lines 260-265):

Values reported from this study fall within previously reported ranges for both CH₄ and CO₂, but maximum CH₄ and CO₂ flux rates in the Red Sea are up to 100 fold below those reported elsewhere. Compiled global values for GHG fluxes range from -16.9 to 629.2 mmol CO₂ m⁻² d⁻¹ and -2.1 to 25,974 µmol CH₄ m⁻² d⁻¹, with mean (±SE) maximum emission rates averaging 202.3 ± 48 mmol m⁻² d⁻¹ and 4783.6 ± 2783 µmol m⁻² d⁻¹ for CO₂ and CH₄ respectively (Table 2).

Including a supplementary map of each field site would help delineate potential differences between the sites. While supplementary visuals would indeed aid in determining site differences, we unfortunately did not record exact core locations, but instead noted distance away from the forest edge, sampling near the center of the mangrove belt in each case. It was our hope that this would minimize spatial differences; regardless we felt the need to include the possibility of spatial variability in our discussion.

As per the reviewer’s suggestion, the referencing error was corrected (now line 376).
Carbon Dioxide and Methane Fluxes at the Air-Sea Interface of Red Sea Mangroves

Abstract

Mangrove forests are highly productive tropical and subtropical coastal systems that provide a variety of ecosystem services, including the sequestration of carbon. While mangroves are reported to be the most intense carbon sinks among all forests, they can also support large emissions of greenhouse gases (GHG), such as carbon dioxide (CO₂) and methane (CH₄), to the atmosphere. However, data derived from arid mangrove systems like the Red Sea are lacking. Here, we report net emission rates of CO₂ and CH₄ from mangroves along the eastern coast of the Red Sea, and assess the relative role of these two gases in supporting total GHG emissions to the atmosphere. Diel CO₂ and CH₄ emission rates ranged from -3452 to 7500 µmol CO₂ m⁻² d⁻¹ and from 0.9 to 13.3 µmol CH₄ m⁻² d⁻¹, respectively. The rates reported here fall within previously reported ranges for both CO₂ and CH₄, but maximum CO₂ and CH₄ flux rates in the Red Sea are 10 to 100-fold below those previously reported for mangroves elsewhere. Based on the isotopic composition of the CO₂ and CH₄ produced, we identified potential origins of the organic matter that support GHG emissions. In all but one mangrove stand, GHG emissions appear to be supported by organic matter from mixed sources, potentially reducing CO₂ fluxes and instead enhancing CH₄ production, a finding that highlights the importance of determining the origin of organic matter in GHG emissions. Methane was the main source of CO₂-equivalents despite the comparatively low emission rates in most of the sampled mangroves, and therefore deserves careful monitoring in this region. Despite the mean net emission of CO₂ and CH₄ by
Red Sea mangroves reported here, these forests become net organic carbon sinks when taking into account the existing carbon burial rates for Red Sea mangroves. By further resolving GHG fluxes in arid mangroves, we will better ascertain the role of these forests in global carbon budgets.
1 Introduction

Mangrove forests, typically growing in the intertidal zones of tropical and subtropical coasts, are highly productive components of coastal ecosystems and adapted to high salinity and anoxic conditions associated with waterlogged sediments. Mangrove forests cover a global estimated area of 137,760 km$^2$ (Giri et al., 2011) and are typically constrained by temperature, with greatest biomass and species diversity in the equatorial zone (Alongi, 2012). Mangroves rank amongst the most threatened ecosystems in the biosphere, with losses estimated at 50% of their global extent over the past 50 years (Alongi, 2012). These losses affect nearly all mangrove regions but the Red Sea, where mangrove coverage has increased by 12% over the past four decades (Almahasheer et al., 2016).

Loss of mangrove forest represents a loss of valuable ecosystem services, including habitat and nursery for marine species, coastal protection from erosion due to wave action, and the filtration of harmful pollutants from terrestrial sources (Alongi, 2008), as well as loss of CO$_2$ sink capacity. Additionally, mangroves can become a source of greenhouse gas (GHG) emissions from disturbed soil carbon stocks (Donato et al., 2011; Alongi, 2014). Hence, mangrove conservation and restoration have been proposed as important components of so-called Blue Carbon strategies to mitigate climate change (Duarte, et al., 2013). Indeed, mangroves are reported to be the most intense carbon sinks among all forests, supporting carbon sequestration rates and organic carbon stocks as much as five times higher than those in terrestrial forests (Donato et al., 2011). While mangrove forests cover less than 1% of total coastal ocean area, they contribute to almost 15% of total carbon sequestration in coastal ecosystems (Alongi, 2012), making mangrove forests highly effective in terms of carbon sequestration per unit area. The management of mangroves to maximize CO$_2$ removal and subsequent storage is gaining momentum as a cost-effective strategy to mitigate climate change.

However, mangrove forests act as both carbon sinks and sources and have been reported to support large GHG emissions in the forms of CO$_2$ and CH$_4$ (Allen et al., 2007; Kristensen et al., 2008a; Chen et al., 2016). Whereas concerns are focused on GHG emissions following mangrove disturbance, estimated at 0.02 – 0.12 Pg C yr$^{-1}$ globally (Donato et al., 2011), undisturbed
mangrove sediments also support GHG emissions (Purvaja and Ramesh, 2000; Kristensen et al., 2008b; Chauhan et al., 2015). Recent reports specifically highlight the importance of methane in flux estimates, as emissions of CH$_4$, with a higher global warming potential, can offset mangrove carbon burial by as much as 20% (Rosentreter et al., 2018b). Previous studies on GHG emission rates either focus on the soil-atmosphere interface, highlighting substantial flux ranges; mangrove sediments show highly variable fluxes, with mangroves reported to act as negligible (Alongi, 2005) to considerable sources (Livesley and Andrusiak, 2012; Chen et al., 2016), or examine net fluxes at the air-sea interface, with few studies in arid systems. Comparisons of carbon sequestration rates between mangrove stands have revealed that climatic conditions play an important role, with mangroves in the arid tropics, such as those in the Red Sea, supporting the lowest carbon sequestration rates (Almahasheer et al. 2017). Likewise, GHG emissions from mangrove forests may vary with climate, with most reported rates to-date derived from the wet tropics (Alongi et al., 2005; Chauhan et al., 2015; Chen et al., 2016). Whereas Red Sea mangroves are considered to play a minor role as CO$_2$ sinks, their role may be greater than portrayed by low carbon burial rates if they also support very low GHG emissions, thereby leading to a balance comparable to mangroves in the wet tropics.

Here we report air-sea emission rates of CO$_2$ and CH$_4$, along with their carbon isotopic composition, from incubations of inundated mangrove sediments cores along the Saudi coast of the Red Sea. We assess the relative role of these two gases in supporting total GHG emissions as well as their fluctuations along the day-night cycle.

2 Materials and Methods

2.1 Study area

We sampled seven mangrove forests along the eastern coast of the Red Sea (Fig. 1). We collected triplicate sediment cores by inserting translucent PVC tubes (30.5 cm in height and 9.5 cm in diameter) into mangrove sediments, collecting approx. 20 cm of sediment and a top seawater layer. The overlying water was regularly replaced by fresh seawater from the corresponding station in order to fill the remaining core volume and to measure CO$_2$ and CH$_4$ fluxes from underlying sediments during incubations. Mangrove sediments were sampled five to
ten meters from the forest edge, typically in the center of the mangrove belt. We sampled two
stations (S1 and S2) in January and February 2017 and the other five mangrove stations (S3-S7)
in March on board the R/V Thuwal as part of a scientific cruise. The cores collected from S1 and
S2 were immediately transported to the laboratory, placed in seawater baths and enclosed in
environmental growth chambers (Percival Scientific Inc., Perry, IA, USA) with 12:12 light
cycles at a constant temperature of 26°C. The sediment cores collected during the scientific
cruise were transported immediately on board and placed in open aquarium tanks with running
seawater in order to keep them close to in situ temperature. Salinity and temperature were
routinely recorded using a CTD. Additionally, sediment chlorophyll a and nutrient (organic
carbon and nitrogen) content were analyzed from cores collected during the scientific cruise.

2.2 Sediment characteristics

The chlorophyll a content of the sediment was measured by fluorometry. The surface layer of
each replicate core was collected and frozen until further analysis. Prior to chlorophyll a
extraction, the sediment samples were left at room temperature to thaw. The chlorophyll a was
extracted by adding 7 ml of 90% acetone to 2 ml of sediment sample. After a 24h incubation at
4°C in dark conditions, the samples were centrifuged and the chlorophyll a content in the
supernatant was measured on a Trilogy fluorometer. The nutrient (organic carbon and nitrogen)
content of the sediment was analyzed on an Organic Elemental Analyzer (Flash 2000) after
acidification of sediment samples.

2.3 Measurement of greenhouse gas fluxes

We measured CO₂ and CH₄ air-sea fluxes using two different techniques. The CO₂ and CH₄
fluxes from stations S1 and S2 were measured using the closed water circuit technique and the
CO₂ and CH₄ fluxes from the rest of the stations sampled during the scientific cruise (S3-S7)
were measured using the headspace technique.

2.3.1 Measurement of CO₂ and CH₄ fluxes in sediment core incubations using
closed water circuit technique
We incubated mangrove sediment cores from stations S1 and S2 using a closed water circuit technique in order to measure changes in CO$_2$ and CH$_4$ concentrations. Before starting the incubation, the seawater above the sediment from each core was replaced by fresh seawater collected from the same location, avoiding disturbance of the sediment. Then, the seawater from the core was recirculated by a peristaltic pump in an enclosed water circuit through a membrane equilibrator (Liqui-cel mini module, 3M, Minnesota, USA). This setup enables the equilibration of gases in dissolution with an enclosed air circuit. The air from the enclosed air circuit was then passed through a desiccant column (calcium sulfate, WA Hammond Drierite Co., LTD, Ohio, USA) and flowed into a cavity ring-down spectrometer (CRDS; Picarro Inc., Santa Clara, CA, USA) to continuously measure the CO$_2$ and CH$_4$ concentration. We ran the incubations for at least 30 minutes under light (200 µmol photons m$^{-2}$ s$^{-1}$) and dark conditions.

The concentration of CO$_2$ in the water circuit (µmol ml$^{-1}$) was calculated by Eq. (1):

$$[CO_2] = H_{cp} x [HP_{CO_2}] x (1 - pH_{20}),$$

where $H_{cp}$ is the Henry constant (mol ml$^{-1}$ atm$^{-1}$) calculated using R marelac package (Soetaert et al., 2016); $[HP_{CO_2}]$ is the given concentration of CO$_2$ (ppm), and pH$_{20}$ is the water vapor pressure (atm).

The CO$_2$ fluxes were calculated from the change in CO$_2$ concentration over time during our incubations, correcting by the seawater volume present in each core. Then, the fluxes were transformed to an aerial basis (µmol m$^{-2}$ h$^{-1}$) by taking into account the core surface area. Finally, the daily fluxes (µmol m$^{-2}$ d$^{-1}$) were calculated by multiplying the CO$_2$ flux obtained under light conditions by the number of light hours plus the CO$_2$ flux obtained under dark conditions by the number of dark hours.

The CH$_4$ fluxes were calculated in the same manner as for the CO$_2$ fluxes, with the exception that the Henry constant was calculated using Eq. (2):

$$\beta = H_{cp} x (RT),$$
where $H_C$ is the Henry constant (mol ml$^{-1}$ atm$^{-1}$), $R$ is the ideal gas constant (82.057338 atm ml mol$^{-1}$ K$^{-1}$), $T$ is standard temperature (273.15 K), and $\beta$ is the Bunsen solubility coefficient of CH$_4$, extracted from Wiesenburg and Guinasso (1979).

### 2.3.2 Measurement of CO$_2$ and CH$_4$ fluxes in sediment core incubations using the headspace technique

Mangrove sediment cores from stations S3 to S7 were incubated using a headspace technique in order to measure changes in CO$_2$ and CH$_4$ concentrations. Before starting the incubation, the seawater above the sediment from each core was replaced by fresh seawater from the running seawater system, leaving a headspace of 200 ml. Each core was sealed with a stopper equipped with a gas-tight valve serving as a headspace sampling port. The sealed core was left for 1 hour before the first headspace sampling to allow equilibration between seawater and air phases. Each core was sampled with a syringe, withdrawing 15 ml of air from the equilibrated headspace. Headspace samples were periodically drawn from each sediment incubation over a 24-hour incubation period. The CO$_2$ and CH$_4$ concentrations in the headspace samples along with their isotopic composition ($\delta^{13}$C-CO$_2$ and $\delta^{13}$C-CH$_4$) were measured with a CRDS (Picarro Inc., Santa Clara, CA, USA) connected to a small sample isotopic module extension (SSIM A0314, Picarro Inc., Santa Clara, CA, USA). We ran standards (730 ppm CO$_2$, 1.9 ppm CH$_4$) before and after every three samples.

The concentration of dissolved CO$_2$ in the seawater after equilibrium was calculated from the concentration in the equilibrated headspace (ppm) as described previously by Wilson et al. (2012) for other gases:

\[
[CO_2]_w = 10^{-6} \beta m_a p_{dry},
\]  \hspace{1cm} (3)

where $\beta$ is the Bunsen solubility coefficient of CO$_2$ (mol ml$^{-1}$ atm$^{-1}$), $m_a$ is the given concentration of CO$_2$ in the equilibrated headspace (ppm), and $p_{dry}$ is atmospheric pressure (atm) of dry air. The Bunsen solubility coefficient of CO$_2$ was calculated using Eq. (4):

\[
\beta = H_C x (RT)
\]  \hspace{1cm} (4)
where \( H_{cp} \) is the Henry constant (mol ml\(^{-1}\) atm\(^{-1}\)) calculated using R marelac package (Soetaert et al., 2016), \( R \) is the ideal gas constant (82.057338 atm ml mol\(^{-1}\) K\(^{-1}\)) and \( T \) is standard temperature (273.15 K). The atmospheric pressure of dry air \( (p_{dry}) \) was calculated using Eq. (5):

\[
p_{dry} = p_{wet} \left(1 - \%H_2O\right)
\] 

where \( p_{wet} \) is the atmospheric pressure of wet air corrected by the effect of multiple syringe draws from the same core, applying Boyle’s law.

The initial concentration of dissolved CO\(_2\) in seawater before equilibrium was then calculated as:

\[
[CO_2]_{aq} = ([CO_2]_w V_w + 10^{-6} m_a V_a) / V_w
\] 

where \([CO_2]_w\) is the concentration of dissolved CO\(_2\) in the seawater after equilibrium, \(V_w\) is the volume of seawater (ml) and \(V_a\) is the headspace volume (ml) in the core. Finally, treating the gas as ideal, the units were converted to nM using Eq. (7):

\[
[CO_2]_{aq} = 10^9 \times p_{dry}[CO_2]_{aq}/(RT)
\] 

where \( R \) is the ideal gas constant (0.08206 atm l mol\(^{-1}\) K\(^{-1}\)) and \( T \) is temperature (K).

The CO\(_2\) fluxes were calculated from the change in CO\(_2\) concentration over time during our incubations, correcting by the seawater volume present in each core. Then, the fluxes were transformed to an aerial basis (\( \mu \)mol m\(^{-2}\) d\(^{-1}\)) by taking into account the core surface area. Finally, the day and night fluxes (\( \mu \)mol m\(^{-2}\) h\(^{-1}\)) were calculated from the change in CO\(_2\) concentration between consecutive samplings during day and night time, respectively.

The CH\(_4\) fluxes were calculated in the same manner as for the CO\(_2\) fluxes, with the exception that the Bunsen solubility coefficient of CH\(_4\) was calculated according to Wiesenburg and Guinasso (1979).

### 2.4 Isotopic composition of CO\(_2\) (\( \delta^{13}C\)- CO\(_2\)) and CH\(_4\) (\( \delta^{13}C\)- CH\(_4\))
The isotopic signature of the CO₂ and CH₄ produced during incubations was estimated by conducting keeling plots (Pataki et al. 2003; Thom et al. 2003; Garcia-Bonet and Duarte 2017). Briefly, the δ¹³C of the CO₂ and CH₄ produced was extracted from the intercept of the linear regression between the inverse of the gas partial pressure and the isotopic signature.

The data set is available from Sea et al. (2018).

3 Results

The mean (± SE) diel CO₂ and CH₄ emission rates for the seven sites were 372 ± 1309 μmol CO₂ m⁻² d⁻¹ and 5.6 ± 1.6 μmol CH₄ m⁻² d⁻¹, respectively. We observed high variability among the seven mangrove forest sites studied, with net CO₂ and CH₄ diel emission rates ranging from -3452 to 7500 μmol CO₂ m⁻² d⁻¹ and from 0.9 to 13.3 μmol CH₄ m⁻² d⁻¹, respectively (Table 1).

Mangrove sediments absorbed CO₂ during daytime and emitted CO₂ during night time at 5 out of 7 stations, with means (± SE) of -54.6 ± 37 μmol CO₂ m⁻² h⁻¹ and 86 ± 120 μmol CO₂ m⁻² h⁻¹ respectively (Table 1, Fig. 2). However, in three out of seven sites, heterotrophic activities outbalanced photosynthesis on a 24h basis. At two sites, S3 and S6, we found an increase of the CO₂ emissions between day and night, contradictory to the classical daytime primary production–night-time respiration pattern, possibly indicative of a light mediated increase of heterotrophic processes.

Methane emissions did not show circadian patterns with linear increases in CH₄ concentration in our incubations (Fig. 2) and with similar light and dark rates (0.26 ± 0.08 and 0.21 ± 0.07 μmol CH₄ m⁻² h⁻¹ (mean ± SE), respectively (Table 1). In terms of total GHG contribution, the mean CO₂-equivalents (CO₂e) emission to the atmosphere was 564 ± 1284 μmol CO₂e m⁻² d⁻¹ (mean ± SE) using the 100 years’ time horizon global warming potential (Myhre et al., 2013). Inundated mangrove sediments were net emitters of CO₂e in three out of seven sites (Table 1), and in five out of seven mangrove stands sampled, CH₄ was the main source of CO₂e to the atmosphere.
While no overall trend was revealed through the relationship between day and night fluxes for CO$_2$ and CH$_4$ (Fig. 3), consistencies are evident at specific mangrove stations. For example, night CO$_2$ emissions are clearly visible at S2, while S3 appears to emit CO$_2$ during daylight hours. No relationship was apparent between GHG fluxes and the densities of organic carbon or nitrogen in the sediment. There was no discernible trend between gas fluxes and chlorophyll a content in surface sediments.

The isotopic signatures of the produced CO$_2$ ($\delta^{13}$C-CO$_2$) ranged from -11.21 to -25.72 ‰ as derived from keeling plots (Fig. 4, Table 1). The $\delta^{13}$C-CO$_2$ was similar for almost all stations, with the exception of S3 that had a $\delta^{13}$C-CO$_2$ of -25.72 ‰. The isotopic composition of the produced CH$_4$ ($\delta^{13}$C-CH$_4$) ranged from -71.28 to -87.08 ‰, with a mean $\delta^{13}$C signature of -80.61 ‰ (Fig. 4, Table 1).

4 Discussion

4.1 Greenhouse gas fluxes

The CO$_2$ and CH$_4$ emissions reported in this study show that Red Sea mangroves can act as a source of GHG to the atmosphere. Values reported from this study fall within previously reported ranges for both CH$_4$ and CO$_2$, but maximum CH$_4$ and CO$_2$ flux rates in the Red Sea are up to 100 fold below those reported elsewhere. Compiled global values for GHG fluxes range from -16.9 to 629.2 mmol CO$_2$ m$^{-2}$ d$^{-1}$ and -2.1 to 25,974 µmol CH$_4$ m$^{-2}$ d$^{-1}$, with mean (±SE) maximum emission rates averaging 202.3 ± 48 mmol m$^{-2}$ d$^{-1}$ and 4783.6 ± 2783 µmol m$^{-2}$ d$^{-1}$ for CO$_2$ and CH$_4$ respectively (Table 2).

The variability in GHG emission rates reported in this study could be attributed to spatial differences, as cores were taken from different parts of each forest. Indeed, previous studies report significant discrepancies in emission rates in fringe versus forest positions (Allen et al., 2007). Additionally it is possible that differences in flux rates may exist as a result of sediment disturbance from the coring process. The effects of mangrove pneumatophores and possible bioturbation from infaunal species such as burrowing crabs were not considered here yet could
pose another possible source of variation in results as the presence of these structures influences oxygenation of sediment and pore water exchange, identified as driving factors in varying CO$_2$ levels (Call et al., 2014; Rosentreter et al., 2018). These factors likely affect relevant redox processes and would therefore be useful to quantify in future studies.

Uniformity of day and night emission rates for CH$_4$ was observed in Red Sea mangrove stands, with mean (± SE) CH$_4$ emission rates of 0.28 ± 0.08 µmol CH$_4$ m$^{-2}$ h$^{-1}$ during the day and 0.24 ± 0.08 µmol CH$_4$ m$^{-2}$ h$^{-1}$ during night; this is consistent with previous work reporting that emission rates for CH$_4$ do not vary significantly during light and dark hours in mangrove forests (Allen et al., 2007). It has been suggested instead that variables such as sediment temperature are more significant in their contributions to emission rates (Allen et al., 2007; Allen et al., 2011).

Incubated sediment cores kept at constant temperature do not reflect the range of temperatures experienced by mangrove sediments over the diurnal cycle; future studies examining GHG emissions under more realistic temperature fluctuations are needed. Seasonal studies of longer duration have reported increased emission rates during warmer seasons (Chen et al., 2016; Livesley and Andrusiak, 2012). Methane concentrations typically remain low due to anaerobic methane oxidation processes that take place near sediment surfaces (Kristensen et al., 2008a), consistent with the low CH$_4$ emission rates from Red Sea mangrove sediments observed here. Additionally, environments of high salinity like the Red Sea have been associated with decreased CH$_4$ emissions, as sulfate-reducing bacteria are thought to outcompete methanogens (Poffenbarger et al., 2011).

Methane emission rates at the air-sea interface of Red Sea mangrove sediments, although quite low, become more substantial when considered in terms of global warming potential. In this study, CH$_4$ was, despite the comparatively low emission rates, the main source of CO$_2$e in the majority of sampled mangroves, and therefore deserves careful monitoring in this region. Reported organic carbon burial rates of Red Sea mangroves of 3.42 mmol C m$^{-2}$ d$^{-1}$ (Almahasheer et al. 2017) are 10 times larger than the combined average CO$_2$ and CH$_4$ emission rates reported here (0.37 mmol C m$^{-2}$ d$^{-1}$), suggesting that these mangrove sediments could act as net atmospheric carbon sinks; however, significant alkalinity and DIC exports have been identified from mangroves as well (Sippo et al., 2016), necessitating future studies which
measure these exports to neighboring habitats in order to close the carbon budget and determine the role of Red Sea mangroves in potential climate change mitigation. Currently, protection measures and further reforestation efforts are being deployed along the Red Sea that will further expand the area of mangroves (Almhasheer et al. 2016). The rationale for conserving mangroves in the climate change context is not adequately represented by their net carbon sink capacity when undisturbed, but rather by the emissions resulting from their disturbance. Indeed, previous studies analyzing anthropogenic impacts on methane emission rates from mangrove sediments have shown that disturbance significantly increases methane emissions (Purvaja and Ramesh, 2001; Chen et al., 2011). This provides an additional rationale to conserve, and continue to expand, Red Sea mangroves.

While this study provides new insights on GHG fluxes from arid mangroves, the methods used here solely measure the air-sea fluxes of dissolved gases. If CO$_2$ is produced from underlying sediments, it enters the water column and becomes a part of the carbonate system, with possibility of conversion to bicarbonate (HCO$_3^-$) and carbonate (CO$_3^{2-}$) ions; these dominating species represent over 99% of the dissolved inorganic carbon (DIC) under current atmospheric and oceanic conditions (Zeebe and Wolf-Gladrow, 2001). Therefore, the air-sea equilibration methods used in this study do not measure DIC fluxes, but only the fluxes of the dissolved CO$_2$ component of this larger system.

Frankignoulle and Borges (2001) show that CO$_2$ can be measured either directly (using equilibrator techniques and spectroscopy or chromatography) or indirectly (by making calculations based on pH, total alkalinity, and DIC). The methodology presented in this study represents the former, utilizing an air-sea equilibrator connected to a CRDS to measure GHG fluxes at the air-sea interface. Research conducted by Borges et al. (2003) utilizes the indirect approach, using pH and total alkalinity measurements in Papua New Guinea to calculate DIC and CO$_2$(dis) (for a computational discussion see Frankignoulle and Borges, 2001). Both methods measure at the air-sea interface (Table Two) but are not directly comparable, as a full determination of the carbonate system was not carried out in the present study. Similarly, studies using equilibrator techniques that measure the dissolved CO$_2$ fraction of seawater to the atmosphere are influenced by the seawater carbonate system and further steps
of isotopic fraction (discussed below), and are therefore not directly comparable to those studies
which measure GHG fluxes from exposed mangrove sediments to the atmosphere (Table Two).

4.2 Isotopic composition of emitted gases

There were no relationships between GHG fluxes and sediment properties, such as chlorophyll \(a\),
nitrogen density, and organic carbon density, suggesting that other factors have greater influence
on GHG flux rates in this region. Since mangroves can receive large contributions of organic
carbon from other sources (Newell et al., 1995), such as algal mats, seagrass and seaweed,
examination of the isotopic composition of emitted carbon provides insights into the origin of the
organic carbon supporting GHG fluxes in mangrove sediments; however, it should be noted that
\(\delta^{13}C\) values reported in this study occur after several steps of isotopic fractionation and may
therefore influence results. Isotope effects can cause an unequal distribution of isotopes between
DIC components; for example as CO\(_2\) is produced from mangrove sediments and becomes part
of the carbonate system (likely forming HCO\(_3^-\) after equilibration), molecules containing the
heavier carbon isotope— with a higher activation energy— will typically react more slowly
(Zeebe and Wolf-Gladrow, 2001), promoting a higher concentration of the heavy isotope in
unreacted CO\(_2\) and a relative depletion of this heavier isotope in resulting HCO\(_3^-\). Similarly, this
preferential incorporation and movement of molecules containing lighter isotopes can affect
resulting carbon isotope ratios after air-sea equilibration (with depletion of lighter isotopes in
seawater as a result of fractionation). CO\(_2\) measured in this study is subject to these processes
and may not reflect the isotopic ratios of carbon originally emitted; rather, the signatures
measured in this study should be seen as a proxy which reflects isotopic ratios of air-sea
discrimination and biological processing (decomposition, respiration, and photosynthesis),
resulting after carbon isotope fractionation. Interpretation of results is therefore subject to this
limitation.

The isotopic signature of the CO\(_2\) (\(\delta^{13}C\)-CO\(_2\)) produced by mangrove sediments in four out of the
five mangrove stands with available isotopic data was heavier (from \(-11.2 \pm 0.6\) to \(-15.9 \pm 1.1\)
‰; Table 1) than the isotopic signature of mangrove tissues, suggesting decomposition of
organic matter from mixed sources (Kennedy et al. 2010). Specifically, the isotopic signature of
the mangroves found in the central Red Sea has been recently reported as $\delta^{13}\text{C}_{\text{leaves}} = -26.98 \pm 0.15 \%$, $\delta^{13}\text{C}_{\text{stems}} = -25.75 \pm 0.16 \%$ and $\delta^{13}\text{C}_{\text{roots}} = -24.90 \pm 0.17 \%$ for mangrove leaves, stems and roots while the mean isotopic signature of other primary producers in the central the Red Sea has been reported as $\delta^{13}\text{C}_{\text{seaweed}} = -12.8 \pm 0.5 \%$ and $\delta^{13}\text{C}_{\text{seagrass}} = -8.2 \pm 0.2 \%$ for seaweed and seagrass tissues, respectively (Almahasheer et al. 2017). However, in one mangrove stand (S3) the $\delta^{13}\text{C}_{\text{CO}_2}$ was much lighter ($-25.72 \pm 0.21 \%$), potentially indicating mangrove tissues. Thus, according to the isotopic signature, the CO$_2$ produced in mangrove sediments would be supported by mangrove biomass in only one mangrove stand out of the five sampled sites with available isotopic data. Moreover, the mean isotopic signature of the CH$_4$ produced in mangrove sediments ($\delta^{13}\text{C}_{\text{CH}_4} = -80.6 \%$) tentatively confirms its biogenic origin, which normally ranges from -40 to -80 \%, depending on the isotopic signature of the organic compounds being biologically decomposed (Reeburgh, 2014). The lowest $\delta^{13}\text{C}_{\text{CH}_4}$ was detected in S3, coinciding with the lowest $\delta^{13}\text{C}_{\text{CO}_2}$ value, suggesting that the organic matter being decomposed by methanogens likely came from mangrove tissues as well.

Interestingly, the mangrove with the lightest $\delta^{13}\text{C}_{\text{CO}_2}$ and $\delta^{13}\text{C}_{\text{CH}_4}$ (S3), showed the lowest daily CO$_2$ flux ($-1524 \pm 686 \mu\text{mol CO}_2 \text{ m}^{-2} \text{ d}^{-1}$) but the highest CH$_4$ emission rate ($13.3 \pm 9.5 \mu\text{mol CH}_4 \text{ m}^{-2} \text{ d}^{-1}$), compared to the fluxes detected in the rest of mangrove stands with available isotopic data. Part of the variability in the CO$_2$ ($R^2 = 0.42$) and CH$_4$ ($R^2 = 0.40$) emission rate seems to be explained by the origin of the organic matter being decomposed, estimated here as the $\delta^{13}\text{C}_{\text{CO}_2}$ and $\delta^{13}\text{C}_{\text{CH}_4}$. Organic matter with lighter isotopic composition could enhance CO$_2$ emissions, whereas organic matter with heavier isotopic composition could enhance CH$_4$ emissions (Fig. 5), possibly suggesting a different preferential use of organic matter by different microbial groups in mangrove sediments. Future studies exploring this idea with further considerations of carbon isotope fractionation would help solidify the role of the origin of organic carbon stored in mangrove sediments on their GHG emissions.

5 Conclusion

This study is first in reporting CO$_2$ and CH$_4$ fluxes from Red Sea mangrove sediments, contributing to the scant data on arid mangrove systems (Atwood et al. 2017, Almahasheer et al.
essential to establish a solid baseline on GHG emissions for future studies. Results show that maximum CO₂ and CH₄ flux rates from Red Sea mangrove sediments are well below those reported elsewhere, and that, even when considered in terms of CO₂ equivalents, carbon burial rates largely outweigh GHG emission rates at the air-sea interface in this region. This study also highlights the importance of determining the source of organic matter in GHG flux studies, as emissions appear to be supported by organic matter from mixed sources in the majority of studied mangroves, potentially enhancing CH₄ production over CO₂ fluxes in this system. Seasonal variation should be considered in future studies on GHG emissions by Red Sea mangroves to better determine annual emission rates from this system, which reaches some of the warmest temperatures experienced by mangrove forests worldwide. Similarly, a wider spatial coverage within the mangrove forest should be considered to confidently determine net GHG fluxes that can be upscaled to the entire stock of Red Sea mangroves.

Methods presented in this study include the use of an air-sea equilibrator connected to a CRDS to measure GHG fluxes at the air-sea interface, measuring the dissolved CO₂ component of the larger seawater carbonate system. This methodology is one of many used to measure GHG flux rates; establishing a unified sampling technique at both the soil-atmosphere and air-seawater interface will aid future researchers in determining total carbon budgets and accurately informing policymakers of their findings. In combination with consideration of isotope effects, a full determination of the carbonate system will be beneficial in future studies to further resolve GHG fluxes in arid mangroves, allowing us to better ascertain the role of these forests in global carbon budgets.

Data availability. All data will be accessible in the repository Pangea pending manuscript acceptance.

Competing interests. The authors declare that they have no conflict of interest.

Author contribution
MAS, NG-B, VS and CMD designed the study. MAS and NG-B performed the measurements and calculations. MAS, NG-B, VS and CMD interpreted the results. All authors contributed substantially to the final manuscript.
