17 **Abstract**

18 Accurate estimates of base cation weathering rates in forest soils are crucial for policy decisions on sustainable  
19 biomass harvest levels and for calculations of critical loads of acidity. The PROFILE model is one of the most  
20 frequently used methods to quantify weathering rates, where the quantitative mineralogical input has often been  
21 calculated by the A2M (“Analysis to Mineralogy”) program based solely on geochemical data. The aim of this  
22 study was to investigate how uncertainties in quantitative mineralogy, originating from modeled mineral  
23 abundance and assumed stoichiometry, influence PROFILE weathering estimate, by using measured quantitative  
24 mineralogy by X-ray powder diffraction (XRPD) as a reference. Weathering rates were determined for two sites,  
25 one in Northern (Flakaliden) and one in Southern (Asa) Sweden. At each site, 3–4 soil profiles were analyzed at  
26 10 cm depth intervals. Normative quantitative mineralogy was calculated from geochemical data and qualitative  
27 mineral data with the A2M program using two sets of qualitative mineralogical data inputs to A2M: 1) A site-  
28 specific mineralogy based on information about mineral identification and mineral chemical composition as  
29 determined directly by XRPD and electron microprobe analyses (EMPA), and 2) regional mineralogy, representing  
30 the assumed minerals present and assumed mineral chemical compositions for large geographical areas in Sweden,  
31 as per previous published studies. Arithmetic means of the weathering rates determined from A2M inputs ( $W_{A2M}$ )  
32 were generally in relatively close agreement with those ( $W_{XRPD}$ ) determined by inputs based on direct XRPD and  
33 EMPA measurements. The hypothesis that using site-specific instead of regional mineralogy will improve the  
34 confidence in mineral data input to PROFILE was supported for Flakaliden. However, at Asa, site-specific  
35 mineralogies reduced the discrepancy for Na between  $W_{A2M}$  and  $W_{XRPD}$  but produced larger and significant  
36 discrepancies for K, Ca and Mg. For Ca and Mg the differences between weathering rates based on different  
37 mineralogies could be explained by differences in the content of some specific Ca- and Mg-bearing minerals, in  
38 particular amphibole, apatite, pyroxene and illite. Improving the accuracy in the determination of these minerals  
39 would reduce weathering uncertainties. High uncertainties in mineralogy, due for example to different A2M  
40 assumptions, had surprisingly little effect on the predicted weathering of Na- and K-bearing minerals. This can be  
41 explained by the fact that the weathering rate constants for the minerals involved, e.g. K-feldspar and micas, are  
42 similar in PROFILE. Improving the description of the dissolution rate kinetics of the plagioclase mineral group as  
43 well as major K-bearing minerals (K-feldspars and micas) should be a priority to help improve future weathering  
44 estimates with the PROFILE model.

45

46

47    **Definitions and abbreviations**

48

49    Mineralogy = the identity (specific mineral or mineral group) and stoichiometry (specific mineral chemical  
50    composition) of minerals that are present at a certain geographic unit, a particular site (*site-specific mineralogy*)  
51    or a larger geographic province (*regional mineralogy*)

52    Quantitative mineralogy= the quantitative information (wt.%) on the abundance of specific minerals in  
53    the soil.

54    **Abbreviations:**

55     $M_{XRPD}$  = quantitative mineralogy based on XRPD (amount) and electron microprobe analysis (composition)

56     $M_{A2M-reg}$  = quantitative mineralogy calculated with the A2M model and using regional mineralogy input

57     $M_{A2M-site}$  = quantitative mineralogy calculated with the A2M model and using site-specific mineralogy input

58     $W_{XRPD}$  = weathering rate based on quantitative mineralogy determined by direct XRPD and electron microprobe  
59    analysis

60     $W_{A2M}$  = weathering rate based on quantitative mineralogy determined by the A2M model (unspecific mineralogy  
61    input)

62     $W_{A2M-reg}$  = weathering rate based on quantitative mineralogy determined by the A2M model, and assuming regional  
63    mineralogy input.

64     $W_{A2M-site}$  = weathering rate based on quantitative mineralogy determined by the A2M model and assuming site-  
65    specific mineralogy input.

68

69        **1. Introduction**

70        The dissolution of minerals in soils and rocks during weathering represents, together with deposition, the most  
71        important long-term supply of base cations for plant growth as well as acting as a buffer against soil and water  
72        acidification. Quantifying weathering rates is therefore of key importance to guide modern forestry demands on  
73        biomass removal by helping to identify threshold levels that are sustainable for base cation removal from soils and  
74        waters. With the introduction of the harvest of forest biomass for energy production that includes whole tree  
75        harvest and stump extraction, about 2–3 times more nutrients are exported from the forest compared to stem-only  
76        harvest. As a result, issues of acidification and base cation supply are exacerbated and the sustainability of this  
77        practice is questioned (Röser, 2008; de Jong et al. 2017). Regional nutrient balance calculations for Sweden have  
78        indicated that net losses of base cations from forest soils can occur in stem-only harvest scenarios, and this trend  
79        would be substantially exacerbated and more frequent in whole-tree harvesting scenarios, largely due to low  
80        weathering rates (Sverdrup and Rosén, 1998; Akselsson et al., 2007a,b). Furthermore, the same effect occurs both  
81        under current and projected future climate conditions (Akselsson et al., 2016).

82        The weathering rates included in these nutrient balance calculations are in most cases based on the PROFILE  
83        model. This is a process-oriented model calculating steady-state weathering rates using transition state theory and  
84        physical and geochemical properties of the soil such as temperature, soil moisture, soil mineralogy and  
85        concentrations of base cation, hydrogen and organic acids. (Sverdrup, 1996). This model has been widely applied  
86        in Europe, Canada and the US during the last several decades or more of weathering research (Olsson et al., 1993;  
87        Langan et al., 1995; Kolka et al., 1996; Starr et al., 1998; Sverdrup and Rosén, 1998; Whitfield et al., 2006;  
88        Akselsson et al., 2007a; Koseva et al., 2010; Stendahl et al., 2013). In some cases nutrient balance calculations  
89        have also been based on the depletion method (Olsson et al., 1993).

90        Reliable weathering rate estimates are crucial for the accuracy of future nutrient budget calculations (Futter et al.,  
91        2012). Regarding the accuracy of the PROFILE model, the importance of high accuracy in physical input  
92        parameters for the modelled weathering rate outputs has been highlighted by Hodson et al. (1996) and Jönsson et  
93        al. (1995). Among the various parameters Hodson et al. (1996) noted that the weathering response of the entire  
94        soil profile depends critically on its mineralogy and as such any choice of the model user about mineralogical input  
95        data may affect the model outcome significantly (Hodson et al., 1997). In most cases the mineralogical input to  
96        the PROFILE model is also derived by modelling yet little attention has been given to the influence of modelled  
97        versus directly measured mineralogical input data on calculated base cation release rates.

98        The most widely used method for direct quantitative mineralogical analysis of soil samples is X-ray powder  
99        diffraction, and the accuracy that can be achieved has been demonstrated in round robin tests most notably the  
100      Reynolds Cup (McCarty, 2002; Kleeberg, 2005; Omotoso et al., 2006, Raven and Self, 2017). Casetou-Gustafson  
101      et al. (2018) made some independent assessment of the accuracy of their own XRPD data by geochemical cross  
102      validation (i.e. the mineral budgeting approach of Andrist-Rangel et al., 2006). Nonetheless, we should stress that  
103      like all analytical methods the determined weight fractions of minerals identified in a soil sample by XRPD will  
104      have an associated uncertainty. Additionally, minerals present in minor amounts, nominally < 1% by weight, may  
105      fall below the lower limit of detection of the XRPD method.

106 Due mainly to the relative ease of measurement and consequent ready availability of total element geochemical  
107 data on soils, indirect methods of determining quantitative soil mineralogy, such as so called ‘normative’  
108 geochemical calculations have been widely used to generate mineralogical data for use in the PROFILE model.  
109 One such method is the normative “Analysis to Mineralogy” (A2M) program (Posch and Kurz, 2007) that has  
110 commonly been used in PROFILE applications (Stendahl et al., 2013; Zanchi et al., 2014; Yu et al., 2016; 2018;  
111 Kronnäs et al., 2019). Based on a quantitative geochemical analysis of a soil sample, typically expressed in weight  
112 percent oxides, as well as on some assessment of the available minerals in the soil sample (minerals present) and  
113 their stoichiometry (chemical compositions), A2M calculates all possible mineralogical compositions for the soil  
114 sample. Thus the A2M output for a given soil sample input has multiple solutions and can be described as a  
115 multidimensional mineralogical solution space. This necessitates a choice when using A2M output in applications  
116 such as weathering rate studies, the convention for which has been to use the geometric mean mineralogical  
117 compositions e.g. Stendahl et al. 2013. Casetou-Gustafson et al. (2018) compared the output of A2M with directly  
118 determined XRPD mineralogies at two sites, applying A2M in two different ways. In the first case the information  
119 on available minerals in the model input was obtained from direct XRPD mineral identifications and information  
120 on mineral stoichiometry from direct microprobe analysis of the minerals at the specific site (hereafter denoted  
121 “site-specific”). In the second case the mineral stoichiometry and mineral identity were both assumed based on an  
122 expert assessment of the probable mineralogy at the regional scale as given by Warfvinge and Sverdrup (1995),  
123 hereafter denoted “regional”. Casetou-Gustafson et al. (2018) concluded that using A2M in combination with  
124 regional input data yielded results with large deviations from directly (XRPD) measured quantitative mineralogy,  
125 particularly for two of the major minerals, K-feldspar and dioctahedral mica. When site-specific mineralogical  
126 input data was used, measured and modeled quantitative mineralogy showed a better correspondence for most  
127 minerals. For a specific mineral and a specific site, however, the bias in determination of quantitative mineralogy  
128 might be significant depending on the accuracy of input data to A2M, i.e. total geochemistry and/or mineral  
129 stoichiometry (Casetou-Gustafson et al., 2018). Potential errors like these in mineralogical input data might be  
130 assumed to affect the calculated weathering for different base cations significantly.

131 In the present study, we used the different mineralogical data from Casetou-Gustafson et al. (2018) to model  
132 weathering rates of soils with the PROFILE model. Rates calculated based on measured mineral abundances using  
133 quantitative XRPD in combination with measured mineral elemental compositions are taken as ‘reference’  
134 weathering rates to which other rates are compared. Samples for this study were collected from podzolised till  
135 soils from 8 soil profiles at two forest sites in northern and southern Sweden, respectively.

136 The primary objective of this study was to describe and quantify the effect of differences in mineralogy input on  
137 PROFILE weathering rates, leaving all other input parameters of the PROFILE model constant to isolate the effects  
138 of variation in input of mineral stoichiometry and abundance. A first specific aim was to determine the  
139 uncertainties in weathering rates caused by uncertainties in normative quantitative mineralogy. This was  
140 approached by comparing PROFILE runs using modeled mineralogies based on the presence of minerals of a  
141 specific site or a larger geographic region (i.e. site-specific and regional mineralogy) with PROFILE runs using  
142 the directly measured mineralogy. The latter was assumed to represent the ‘true’ mineralogy at each site. The  
143 comparison of PROFILE weathering rates, based on XRPD versus A2M mineralogy, was done using 1000 random  
144 solutions per sample from the entire multidimensional A2M mineralogical solution space. In the following,

145 weathering rates calculated by PROFILE based on XRPD and A2M mineralogies are denoted  $W_{XRPD}$  and  $W_{A2M}$ ,  
146 respectively.

147 A second specific aim was to investigate how the over- or underestimation of  $W_{A2M}$  in relation to  $W_{XRPD}$  mirrors  
148 the over- or underestimation of mineral contents estimated with A2M.

149 The following hypotheses were made:

150 (1) PROFILE weathering rates obtained with normative quantitative mineralogy calculated based on site-specific  
151 mineralogical information about mineral identity and mineral stoichiometry, are more similar to the reference  
152 weathering rates than PROFILE runs obtained with normative quantitative mineralogy calculated based on  
153 regional information only.

154 (2) Over- and underestimations of weathering rates of different base cations by the PROFILE model can be  
155 explained by over- or underestimations of mineral contents of a few specific minerals.

156

## 157 **2. Materials and methods**

### 158 **2.1 Study sites**

159 Two experimental forest sites, Asa in southern, and Flakaliden in northern Sweden, were used for the study (Table  
160 1). Both sites have Norway spruce (*Picea abies* (L.) Karst) stands of uniform age, but differ in climate. Flakaliden  
161 is located in the boreal zone with long cold winters, whereas Asa is located in the hemiboreal zone. The soils have  
162 similar texture (Sandy loamy till), soil types (Spodosols) and moisture conditions. According to the geographical  
163 distribution of mineralogy types in Sweden the sites belong to different regions (Warfvinge and Sverdrup, 1995).  
164 The experiments, which started in 1986, aimed at investigating the effects of optimized water and nutrient supply  
165 on tree growth and carbon cycling in Norway spruce forests (Linder 1995, Albaugh et al. 2009). The sites are  
166 incorporated in the Swedish Infrastructure for Ecosystem Science (SITES).

### 167 **2.2 Soil sampling and stoniness determination**

168 Soil sampling was performed in October 2013 and March 2014 in the border zone of four plots each of the sites.  
169 Plots selected for sampling were untreated control plots (K1 and K4 at Asa, 10B and 14B at Flakaliden) and  
170 fertilized 'F' plots (F3, F4 at Asa, 15A, 11B at Flakaliden). A rotary drill was used in order to extract one intact  
171 soil core per plot (17 cm inner diameter) except for plot K4, F3 and F4 at the Asa site. A 1 x 1m soil pit was  
172 excavated at each of the three latter plots due to inaccessible terrain for forest machinery. The maximum mineral  
173 soil depth varied between 70–90 cm in Flakaliden and 90–100 cm in Asa.

174

175 The volume of stones and boulders was determined with the penetration method by Viro (1952), and by applying  
176 penetration data to the functions by Stendahl et al. (2009). A metal rod was penetrated at 16 points per plot into  
177 the soil until the underground was not possible to penetrate any further, or to the depth 30 cm. There was a higher  
178 average stoniness at Flakaliden than Asa (39 vol-% compared to 29 vol-% in Asa) that could partially explain the  
179 lower maximum sampling depth at Flakaliden.

180    **2.3 Sample preparation**

181    Soils samples for chemical analyses were taken at 10 cm depth intervals in the mineral soil. Prior to analysis all  
182    soil samples were dried at 30–40 °C and sieved at 2 mm mesh. Soil chemical analyses were performed on the fine  
183    earth fraction (< 2mm).

184    **2.4 Analysis of geochemistry, total carbon and soil texture**

185    Total carbon was determined using a LECO elemental analyzer according to ISO 10694. Analysis of total  
186    geochemical composition, conducted by ALS Scandinavia AB, was made by inductively coupled plasma  
187    spectrometry (ICP-MS). Prior to analyses, the samples were ignited at 1000° C to oxidize organic matter and  
188    grinded with an agate mortar. Particle size distribution was analyzed by wet sieving and sedimentation (Pipette  
189    method) in accordance with ISO 11277. More details about the analytical procedure was given by Casetou-  
190    Gustafson et al. (2018).

191    **2.5 Determination of quantitative mineralogy**

192    A detailed description of methods used to quantify mineralogy of the samples was given by Casetou et al. (2018)  
193    and these are described in brief below.

194    **2.5.1 Measured mineralogy**

195    Quantitative soil mineralogy was determined with the X-ray powder diffraction technique, XRPD ( $M_{XRPD}$ ) (Hillier  
196    1999, 2003) (Table S1a-b). Preparation of samples for determination of XRPD patterns was made from spray  
197    drying slurries of micronized soil samples (<2 mm) in ethanol. Quantitative mineralogical analysis of the  
198    diffraction data was performed using a full pattern fitting approach (Omotoso et al., 2006). In the fitting process,  
199    the measured diffraction pattern is modelled as a weighted sum of previously recorded and carefully verified  
200    standard reference patterns of the prior identified mineral components. The chemical composition of the various  
201    minerals present in the soils was determined by electron microprobe analysis (EMPA) (Table S6).

202    **2.5.2 Calculated mineralogy**

203    The A2M program (Posch and Kurz, 2007) was used to calculate quantitative mineralogical composition ( $M_{A2M}$ )  
204    from geochemical data. Based on a set of pre-determined data on mineral identity and stoichiometry, the model  
205    outcome is a range of equally possible mineralogical compositions. The multidimensional structure of this  
206    normative mineralogy model is a consequence of the number of minerals being larger than the number of analysed  
207    elements, where a specific element can often be contained in several different minerals. A system of linear  
208    equations is used to construct an M-N dimensional solution space (Dimension M= Number of minerals, Dimension  
209    N=number of oxides). In this study we used one thousand solutions to cover the range of possible quantitative  
210    mineralogies that may occur at a specific site.

211

212    A2M was used to calculate 1000 quantitative mineralogies each for two different sets of mineral identity and  
213    element stoichiometry,  $M_{A2M-reg}$  (regional) and  $M_{A2M-site}$  (site-specific). Regional mineralogy refers to the mineral  
214    identity and stoichiometry for the four major mineralogical provinces in Sweden as suggested by Warfvinge and  
215    Sverdrup (1995), of which Asa and Flakaliden belong to different regions (Table S5). Site-specific mineralogy

216 refers to the measured mineral identity and stoichiometry determined by the XRPD and electron microprobe  
217 analyses of the two sites (Table S6) (Casetou-Gustafson et al., 2018).

218 **2.6. Estimation of weathering rates with PROFILE**

219 **2.6.1 PROFILE model description**

220 The biogeochemical PROFILE model can be used to study the steady state weathering (i.e. stoichiometric mineral  
221 dissolution) of soil profiles, as weathering is known to be primarily determined by the physical soil properties at  
222 the interface of wetted mineral surfaces and the soil solution. PROFILE is a multilayer model, thus, for each soil  
223 layer, parameters are specified based on field measurements and estimation methods (Warfvinge and Sverdrup,  
224 1995). Furthermore, isotropic, well mixed soil solution conditions are assumed to prevail in each layer as well as  
225 surface limited dissolution in line with early views by Aagard and Helgeson (1982) and Cou and Wollast (1985)  
226 (Sverdrup, 1996). Based on these major assumptions, PROFILE calculates chemical weathering rates from a series  
227 of kinetic reactions that are described by laboratory determined dissolution rate coefficients and soil solution  
228 equilibria (i.e. transition state theory) (Sverdrup and Warfvinge, 1993). The PROFILE version (September 2018)  
229 that was used in this study is coded to produce information on the weathering contribution of specific minerals,  
230 which allowed us to test our second hypothesis. This version is based on the weathering rates of 15 minerals. Of  
231 these, apatite, pyroxene, illite, dolomite and calcite were not found at the two study sites according to XRPD data  
232 (Table S1).

233 **2.6.2 PROFILE parameter estimation**

234 The only parameter that was changed between different PROFILE runs was the quantitative mineralogy for each  
235 soil layer, as described above. Hence, PROFILE estimated weathering rates ( $W$ ) based on measured mineralogy  
236 ( $W_{XRPD}$ ), and the two versions of A2M calculated mineralogy, regional ( $W_{A2M-reg}$ ), and site-specific ( $W_{A2M-site}$ ). In  
237 the regional mineralogy, plagioclase is assumed to occur as pure anorthite and pure albite for simplification as has  
238 been used in previous studies (Stendahl et al., 2013; Zanchi et al., 2014). This simplification was done in order to  
239 avoid having a number of minerals containing different amount of Ca and Na, as a result of plagioclase forming a  
240 continuous solid solution series, since it would not affect the weathering rates.

241

242 The physical soil layer specific parameters, that were kept constant between different profile runs, were exposed  
243 mineral surface area, stoniness, soil bulk density and soil moisture (Table 2). Exposed mineral surface area was  
244 estimated from soil bulk density and texture analyses in combination with an algorithm specified in Warfvinge  
245 and Sverdrup (1995) and critically discussed in Hodson et al. (1998). The volumetric field soil water content in  
246 Flakaliden and Asa was estimated to be  $0.25 \text{ m}^3 \text{ m}^{-3}$  according to the moisture classification scheme described in  
247 Warfvinge and Sverdrup (1995). It was used to describe the volumetric water content for each soil pit.

248

249 Another group of parameters kept constant was chemical soil layer specific parameters. Aluminum solubility  
250 coefficient needed for solution equilibrium reactions, defined as  $\log\{\text{Al}^{3+}\} + 3\text{pH}$ , was estimated applying a  
251 function developed from previously published data (Simonsson and Berggren, 1998) on our own total carbon and  
252 oxalate extractable aluminum measurements. The function is based on the finding that the Al solubility in the  
253 upper B-horizon of Podzols is closely related to the molar ratio of aluminum to carbon in pyrophosphate extracts,

254 and that below the threshold value of 0.1, Al solubility increases with the  $\text{Al}_p/\text{C}_p$  ratio (Simonsson and Berggren,  
255 1998). Thus, a function was developed for application to our own measurements of  $\text{Al}_{\text{ox}}$  and  $\text{C}_{\text{tot}}$  based on the  
256 assumption that it is possible to use the  $\text{Al}_{\text{ox}}/\text{C}_{\text{tot}}$  ratio instead of the  $\text{Al}_p/\text{C}_p$  ratio. Data on soil solution DOC were  
257 available from lysimeters installed at 50 cm depth for plot K4 and K1 in Asa and 10B and 14B in Flakaliden, and  
258 these values were also applied to soil depths below 50 cm (H. Grip, unpublished data). The E-horizon (0 –10 cm  
259 at Flakaliden) and A-horizon (0 –10 cm at Asa) were characterized by higher DOC values based on previous  
260 findings (Fröberg et al., 2013) and the classification scheme of DOC in Warfvinge and Sverdrup (1995). Partial  
261  $\text{CO}_2$  pressure values in the soil were taken from the default estimate of Warfvinge and Sverdrup (1995).

262

263 Other site-specific parameters that were kept constant between PROFILE runs were evapotranspiration,  
264 temperature, atmospheric deposition, precipitation, runoff and nutrient uptake. Temperature is one of the important  
265 factors that regulate the weathering rate, and for steady-state calculations in PROFILE the mean annual  
266 temperature is used. Kronnäs et al. (2019) demonstrates how weathering rates varies between seasons, due to e.g.  
267 variations in temperature. Precipitation is used in PROFILE to calculate vertical water flow through the soil profile.  
268 The main effect of precipitation on weathering rates is its impact on soil moisture, but in PROFILE soil moisture  
269 is not internally modeled, but given as input. An estimate of the average evaporation per site was derived from  
270 annual averages of precipitation and runoff data using a general water balance equation. Deposition data from two  
271 sites of the Swedish ICP Integrated Monitoring catchments, Aneboda (for Asa) and Gammtratten (for Flakaliden)  
272 (Löfgren et al., 2011) were used to calculate the total deposition. The canopy budget method of Staelens et al.  
273 (2008) was applied as in Zetterberg et al. (2014) for  $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ ,  $\text{K}^+$ ,  $\text{Na}^+$ . The canopy budget model is commonly  
274 used for elements that are prone to canopy leaching ( $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ ,  $\text{K}^+$ ,  $\text{Na}^+$ ,  $\text{SO}_4^{2-}$ ) or canopy uptake ( $\text{NH}_4^+$ ,  $\text{NO}_3^-$ )  
275 and calculates the total deposition (TD) as the sum of dry deposition (DD) and wet deposition (WD). Wet  
276 deposition was estimated based on the contribution of dry deposition to bulk deposition, both for base cations and  
277 anions, using dry deposition factors from Karlsson et al. (2012, 2013). Base cation and nitrogen accumulation rate  
278 in above-ground tree biomass (i.e. bark, stemwood, living and dead branches, needles) was estimated as the  
279 average accumulation rate over a 100 years rotation length in Flakaliden compared to a 73 years rotation length in  
280 Asa. These calculations were based on Heureka simulations using the StandWise application (Wikström et al.,  
281 2011) for biomass estimates in combination with measured nutrient concentrations in above-ground biomass (S.  
282 Linder unpubl. data).

## 283 2.7 A definition of significant discrepancies between $\text{W}_{\text{A2M}}$ and $\text{W}_{\text{XRPD}}$

284 A consequence of the mathematical structure of the A2M program is that the final solution space of possible  
285 quantitative mineralogies produces an uncertainty range of weathering estimates, but in a different sense than the  
286 uncertainty caused by e.g. uncertainties in chemical analyses, because all mineralogies produced within this range  
287 are equally likely. Thus, here we define a significant discrepancy between  $\text{W}_{\text{XRPD}}$  and  $\text{W}_{\text{A2M}}$  to occur when the  
288 former is outside the range of the latter, as illustrated in Fig. 1a. The opposite case is a non-significant discrepancy,  
289 when the weathering rates based on XPRD are contained in the weathering range based on A2M (Figure 1b).

290

291 The uncertainty range of  $\text{W}_{\text{A2M}}$  can potentially be reduced by reducing uncertainties in analyses of soil  
292 geochemistry but most particularly by definitions of available minerals and their stoichiometry. Furthermore, some

293 discrepancies between  $W_{XRPD}$  and  $W_{A2M}$  might also arise due to limitations of the XRPD method, particularly  
294 when minerals occur near or below the detection limit.

295 **2.8 Statistical analyses**

296 In order to quantify the effect of mineralogy on PROFILE weathering rates two statistical measures were used to  
297 describe the discrepancies between  $W_{XRPD}$  and  $W_{A2M}$ . Firstly, root mean square errors (RMSE) of the differences  
298 between  $W_{XRPD}$  and the arithmetic mean of weathering rates based on regional and site-specific mineralogy, i.e.,  
299  $W_{A2M-reg}$  and  $W_{A2M-site}$ , were calculated:

300

301 
$$RMSE = \sqrt{\frac{1}{n} \sum_{i=1}^n (W_{XRPD_i} - W_{A2M_i})^2} \quad \text{Eq. (1)}$$

302

303 RMSE's were calculated individually for each element, soil layer and soil profile for two data sets. An RMSE  
304 expressing the error of the aggregated, total weathering rates in the 0–50 cm soil horizon was calculated to test our  
305 first hypothesis (RMSE of total weathering). In addition, an RMSE expressing the errors originating from  
306 discrepancies between  $W_{XRPD}$  and  $W_{A2M}$  for individual minerals was also calculated (RMSE of weathering by  
307 mineral). In the latter case, sums of RMSE's by mineral were calculated for each element and soil profile by  
308 analogy with the summing up of weathering rates for the whole 0–50 cm soil profile.

309

310 Secondly, relative discrepancies (i.e. average percentage of over- or underestimation of  $W_{A2M}$  compared to  $W_{XRPD}$ )  
311 were calculated as the absolute discrepancy divided by the measured value.

312

313 
$$\text{Relative error} = \left( \frac{W_{A2M_i} - W_{XRPD_i}}{W_{XRPD_i}} \right) 100 \quad \text{Eq. (2)}$$

314

315 Relative errors were calculated for each site by comparing the average sum of  $W_{A2M}$  in the upper mineral soil (0–  
316 50 cm) with the sum of  $W_{XRPD}$  in the upper mineral soil.

317 Statistical plotting of results was performed using R (version 3.3.0) (R Core Team, 2016) and Excel 2016.

318 **3. Results**

319 **3.1 Weathering rates based on XRPD mineralogy**

320 Weathering estimates with PROFILE are hereafter presented as the sum of weathering rates in the 0–50 cm soil  
321 horizon, since this soil depth is commonly used in weathering rate studies. Information on individual, and deeper  
322 soil layers (50–100 cm) is given in Table S2.

323

324 Weathering rates of the base cations based on quantitative XRPD mineralogy ( $W_{XRPD}$ ), i.e. the reference  
325 weathering rates, were ranked in the same order at both sites, with Na>Ca>K>Mg (Table S2). On average,  
326 weathering rates of Na, Ca, K and Mg at Asa were 17.7, 8.4, 5.6 and 3.6 mmol<sub>c</sub> m<sup>-2</sup> yr<sup>-1</sup>, respectively.  
327 Corresponding figures for Flakaliden were of similar magnitude, i.e., 14.8, 9.8, 5.7 and 5.6 mmol<sub>c</sub> m<sup>-2</sup> yr<sup>-1</sup>. The  
328 variation in weathering rates between soil profiles was smaller at Asa than at Flakaliden, as the standard deviation

329 in relation to the means for different elements ranged between 0.2–2.3 at Asa, and 2.0–5.7 at Flakaliden (Table  
330 S2).

331

### 332 **3.2 Comparison between weathering rates based on XRPD and A2M mineralogy**

333 At Flakaliden,  $W_{A2M\text{-site}}$  was generally in closer agreement with  $W_{XRPD}$  than  $W_{A2M\text{-reg}}$  (Fig. 2b), in line with the first  
334 hypothesis. The discrepancies between  $W_{XRPD}$  and  $W_{A2M}$  were small and non-significant for Mg regardless of the  
335 mineralogy input used in A2M, although the estimated discrepancies were reduced when site-specific mineralogy  
336 was used. The use of regional mineralogy in A2M underestimated K release rates compared to  $W_{XRPD}$ , and the  
337 discrepancy was significant. Using site-specific mineralogy resulted in smaller and non-significant discrepancy  
338 for K release rates. A similar response to different mineralogies was revealed for Ca, although the result varied  
339 more among soil profiles. In contrast to K and Ca, the release of Na was overestimated by both  $W_{A2M\text{-site}}$  and  $W_{A2M\text{-reg}}$   
340 compared to  $W_{XRPD}$ . The discrepancies were significant regardless of the mineralogy input used in A2M,  
341 although using site-specific mineralogy slightly reduced the discrepancy. The generally closer agreement between  
342  $W_{A2M\text{-site}}$  and  $W_{XRPD}$  than  $W_{A2M\text{-reg}}$  at Flakaliden was also indicated by the lower RMSEs of total weathering for all  
343 base cations when site-specific mineralogy was used (Fig. 3a). Relative RMSE were below 20 % for  $W_{A2M\text{-reg}}$ , but  
344 below 10 % for  $W_{A2M\text{-site}}$ . However, RMSE for Na was only slightly smaller for  $W_{A2M\text{-site}}$  than  $W_{A2M\text{-reg}}$  (16 % for  
345  $W_{A2M\text{-site}}$ ).

346

347 PROFILE weathering rates for Asa revealed a different pattern compared to Flakaliden, and the results for Ca, Mg  
348 and K were contradictory to hypothesis one.  $W_{A2M\text{-reg}}$  was in close agreement with  $W_{XRPD}$  for K, Ca and Mg, and  
349 the small discrepancies were non-significant (Fig. 2a). However,  $W_{A2M\text{-reg}}$  for Na was consistently overestimated  
350 compared to  $W_{XRPD}$  and the discrepancies were significant. Using site-specific mineralogy improved the fit  
351 between  $W_{XRPD}$  and  $W_{A2M}$  for Na but had rather the opposite effect on the other base cations at this site. For K, Ca  
352 and Mg,  $W_{A2M\text{-site}}$  overestimated weathering rates, and resulted in significant discrepancies, and larger RMSE,  
353 whereas the discrepancies for Na were reduced and non-significant (Fig. 3a). At Asa, the highest relative RMSEs  
354 of total weathering occurred for Ca and Mg with  $W_{A2M\text{-site}} (> 30 \%)$  (Fig. 3a). Large standard deviations were due  
355 to a single soil profile, F4. The better consistency with  $W_{A2M\text{-reg}}$  was indicated by RMSE below 10 % for Ca and  
356 Mg, and that RMSE for Mg was half of the error with  $W_{A2M\text{-site}}$ . Only for Na, RMSE was lower for  $W_{A2M\text{-site}}$  than  
357 with  $W_{A2M\text{-reg}}$ .

358

359 A complementary illustration of the relationships between weathering rates based on XRPD and A2M is shown in  
360 Fig. 4 and provided as Tables S3 and S4, which includes all data from individual soil layers 0–50 cm. A general  
361 picture is that  $W_{A2M\text{-site}}$  was less dispersed along the 1:1-line than  $W_{A2M\text{-reg}}$ , in particular for Flakaliden. On the  
362 other hand, for weathering rates in the lower range ( $< 5 \text{ mmol}_c \text{ m}^{-2} \text{ yr}^{-1}$ ) site-specific mineralogy tended to generate  
363 both over- and underestimated weathering rates. In most soil profiles, deviations from the 1:1-line were frequent  
364 in soil layers below 20 cm. For Na under- and overestimations occurred in the whole range of weathering  
365 estimates,

366 **3.3 Mineral-specific contribution to weathering rates**

367 In spite of its intermediate dissolution rate plagioclase was, due to its abundance, the most important Na-bearing  
368 mineral determined in this study (Table 3 and Fig. 5). Plagioclase is a variable group of minerals with different  
369 stoichiometric proportions of Ca and Na, from the purely sodic albite on the one hand to the purely calcic anorthite  
370 on the other hand (Table S5) as well as with intermediate compositions (Table S6). For simplicity, they will be  
371 referred to in this study as sodic and calcic plagioclase. Based on the same quantitative mineralogy (i.e. same  
372 elemental compositions and identity of minerals),  $W_{XRPD}$  and  $W_{A2M\text{-site}}$  gave strong weight to both calcic and sodic  
373 plagioclase in estimating Na release rates, but  $W_{A2M\text{-site}}$  gave stronger weight to calcic versus sodic plagioclase at  
374 Asa, and vice-versa at Flakaliden (Fig. 5). In spite of these differences, the resultant release rates of Na according  
375 to  $W_{A2M\text{-site}}$  and  $W_{XRPD}$  were rather similar (Fig. 5).

376

377 Total Na release rates of  $W_{A2M\text{-reg}}$  compared to  $W_{XRPD}$  were moderately overestimated. The relative RMSE of  
378 weathering by specific Na-containing minerals were of more similar magnitude for Na at Flakaliden compared to  
379 Asa (Fig. 3b). However, the standard deviations of RMSE were relatively large at Flakaliden, due to large RMSE  
380 for albite in one specific soil profile (11B) (Table S7). Contrary to relative RMSE of total weathering, the relative  
381 RMSE of weathering by specific minerals was lower for Na at Asa with regional than site-specific mineralogy.

382

383 According to  $W_{XRPD}$ , calcic plagioclase weathering was the most important source to Ca release at Flakaliden, and  
384 the second most important source at Asa after epidote (Fig. 5). As for Na,  $W_{A2M\text{-site}}$  gave stronger weight to calcic  
385 plagioclase than  $W_{XRPD}$  at Asa. It was the other way around for  $W_{A2M\text{-site}}$  at Flakaliden and the regional mineralogy  
386 (i.e.  $W_{XRPD}$  gave stronger weight to calcic plagioclase than  $W_{A2M\text{-site}}$ ). Another important Ca source in weathering  
387 estimates based on A2M was apatite. This mineral was not detected in the XRPD analyses but was included in  
388 both A2M mineralogies as a necessary means to allocate measured total phosphorus content to a specific mineral  
389 (Casetou-Gustafson et al. 2018).

390

391 Similar to Na, relative RMSE of weathering by Ca-containing minerals were several magnitudes larger than RMSE  
392 of the total weathering of Ca. In other words, although an overall similar weathering rates might be generated by  
393 the PROFILE model based on different quantitative mineralogies, the underlying modelled contributions from  
394 different minerals can be markedly different. At Flakaliden, the mean relative RMSE by specific minerals were  
395 larger for regional than site-specific mineralogy at Flakaliden (Fig. 3b). However, the difference was not  
396 significant since the standard deviations were high, probably due to larger RMSE for Ca-bearing minerals in soil  
397 profile 11B (Table S7).

398

399 A general picture of the mineral contribution to Mg release is that  $W_{XRPD}$  placed most weight to amphibole whereas  
400 in  $W_{A2M}$  Mg release was more equally distributed among other minerals, notably hydrobiotite, trioctahedral mica  
401 and vermiculite. At Asa, and to an even larger extent at Flakaliden, Mg release by A2M mineralogies was  
402 determined by a higher contribution of minerals with high dissolution rates (Fig. 5 and Table 3) (i.e. In  $W_{A2M\text{-site}}$ ,  
403 hydrobiotite and trioctahedral mica; In  $W_{A2M\text{-reg}}$ , muscovite and vermiculite at Asa and biotite and illite at  
404 Flakaliden). At Asa, less weight was given to amphibole by  $W_{A2M\text{-site}}$  compared to  $W_{XRPD}$ . At Flakaliden, the  $W_{A2M\text{-site}}$   
405 was close  $W_{XRPD}$  in spite of the very different allocations of weathering rates to different minerals. The

underestimation of Mg release by  $W_{A2M-reg}$  was largely explained by the lower weight given to amphibole in both A2M scenarios (Fig. 5). However, A2M gave larger weight to other minerals. The sums of RMSEs of weathering from specific Mg-bearing minerals were much larger for regional than site-specific mineralogy at Flakaliden and reached a maximum value of 156 %. A contributing factor were generally larger RMSE for the mineral contribution of amphibole to Mg weathering and the fact that pyroxene contributed to the RMSEs of the total weathering of Mg. Furthermore, a large standard deviation for the sum of RMSE of specific minerals (Fig. 3b) was caused by soil profile 11B where more weight was placed on amphibole and biotite in contributing to Mg weathering (Table S7). The two A2M mineralogies resulted in the same RMSEs for Mg-bearing minerals at Asa (Fig. 3b).

Potassium release rates were largely dominated by K-Feldspar weathering in both  $W_{XRPD}$  and  $W_{A2M-site}$ . However, K release by  $W_{A2M-reg}$  (Fig. 5) were largely determined by micas at both sites. Together with Mg, these elements had also the lowest weathering rates, indicating that differences between  $W_{A2M-reg}$  and  $W_{XRPD}$  in relative terms were not correlated with the magnitude of weathering. Unlike the other base cations, relative RMSE of K-bearing minerals were lower at both sites when site-specific mineralogy was used instead of regional (Fig. 3b), and the mineral specific RMSEs were also of similar magnitude as the RMSE of the total weathering (Fig. 3a).  $W_{A2M-site}$  of K (Fig. 3b), were not several magnitudes larger than RMSE of the total weathering (Fig. 3a). The largest relative RMSEs of K-containing minerals were reached by  $W_{A2M-reg}$  at Flakaliden in soil profile 11B, indicated by the high standard deviation.

#### 4. Discussion

##### 4.1 General range of weathering rates in relation to expectations from other sensitivity studies, and the range of discrepancies between $W_{XRPD}$ and $WA2M$

To our knowledge, the present study is the first to have examined the sensitivity of the PROFILE model on real case study differences of directly measured mineralogy versus indirectly determined normative mineralogy. However, a few systematic studies have been made previously to test the influence of mineralogy inputs, amongst other input parameters, to PROFILE weathering rates. Jönsson et al. (1995) concluded that uncertainty in quantitative mineralogy could account for a variation from the best weathering estimate of about 20 %, and that variations in soil physical and chemical parameters could be more important. The sensitivity analysis of Jönsson et al. (1995) was made by a Monte Carlo simulation where mineralogical inputs were varied by  $\pm 20\%$  of abundant minerals, and up to  $\pm 100\%$  of minor minerals. Shortly after, Hodson et al. (1996) examined the sensitivity of the PROFILE model with respect to the sensitivity of weathering of specific minerals and concluded that large uncertainties especially in soil mineralogy, moisture, bulk density, temperature and surface area determinations will have a larger effect on weathering rates than was reported by Jönsson et al. (1995).

Compared with the sensitivity analyses by Jönsson et al. (1995), the range of uncertainty in dominating mineral inputs used in the present study was of similar order of magnitude. For this study we used the XRPD measured ( $M_{XRPD}$ ) and A2M estimated mineralogies ( $M_{A2M}$ ) determined by Casetou-Gustafson et al. (2018). For example, they concluded that  $M_{A2M-reg}$  produced a low relative RMSE of total plagioclase (7 – 11 %) but higher relative RMSE for less abundant minerals, such as dioctahedral mica (90 – 106 %). They also showed that when regional

444 mineral identity and assumed stoichiometry was replaced by site-specific mineralogy ( $M_{A2M-site}$ ), the bias in  
445 quantitative mineralogy was reduced.

446 Thus, given this bias in quantitative mineralogy input to PROFILE, discrepancies of  $W_{A2M}$  from  $W_{XRPD}$  at our  
447 study sites should have been on the order of 20 % or less, and site-specific mineralogy inputs should produce  
448 weathering rates with lower discrepancies than regional mineralogy. The result of this study was in agreement  
449 with this expectation for all elements at Flakaliden but only for Na at Asa. The different quantitative mineralogies  
450 resulted in discrepancies between  $W_{A2M}$  and  $W_{XRPD}$  that differed with site (Fig. 3a, 5).

451 **4.2 Is  $W_{A2M-site}$  more consistent than  $W_{A2M-reg}$ ?**

452 Our first hypothesis, that using site-specific mineralogy in the PROFILE model compared to regional mineralogy,  
453 should result in weathering rates closer to XRPD-based mineralogy, and thus be more consistent, was generally  
454 supported for Flakaliden, but only for Na at Asa. This result was revealed from both the occurrence of significant  
455 discrepancies as well as the RMSE of the total weathering rates. Thus, the results did not support our first  
456 hypothesis in a consistent way. The possible reasons for this outcome are discussed below, based on the analysis  
457 of how different minerals contributed to the overall weathering rates.

458 **4.3 How are discrepancies between  $W_{A2M}$  and  $W_{XRPD}$  correlated to bias in determinations of quantitative  
459 mineralogy**

460 The version of the PROFILE model used in this study allowed a close examination of the per element weathering  
461 rate contributions obtained from different minerals that provide some insight into the causes to the total  $W_{A2M}$   
462 discrepancies.

463 **4.3.1 Sodium release rates**

464 A biased determination of mineralogy may not necessarily result in a corresponding bias of PROFILE weathering  
465 estimates if the discrepancies are cancelling each other out, and if dissolution rates of the different minerals are  
466 rather similar. This was probably the case for Na. At both study sites and for both  $W_{XRPD}$  and  $W_{A2M}$ , Na release  
467 rates were largest for plagioclase minerals. The Na release from  $W_{A2M-site}$  and  $W_{A2M-reg}$  were close to  $W_{XRPD}$  at both  
468 study sites (i.e. all weathering rates were in the range of 17-19 mmol<sub>c</sub> m<sup>-2</sup> yr<sup>-1</sup>) nonetheless  $W_{A2M-site}$  placed more  
469 weight to calcic plagioclase and  $W_{A2M-reg}$  more weight to albitic plagioclase (Fig.5). Contrary to our second  
470 hypothesis, the relatively high precision in total release rates (i.e.<10%; Fig. 3a) of Na was not correlated to the  
471 actual low precision in mineral contribution to the total Na release rates (i.e. >30%; Fig. 3b). The latter can be  
472 explained by the fact that in PROFILE all types of plagioclase have the same dissolution rate coefficients (Table  
473 3). Due to this, and in combination with the fact that plagioclase type minerals are a major source for Na, the  
474 mineralogical uncertainty in estimating Na release rates with PROFILE was relatively low in this study (i.e. <20  
475 %). In context, however, we note that it is generally accepted that under natural conditions different plagioclase  
476 minerals weather at different rates, (Allen and Hajek, 1989, Blum and Stillings, 1995).

477 **4.3.2 Calcium release rates**

478 According to  $W_{XRPD}$  and  $W_{A2M}$ , a key mineral for Ca release rates was calcic plagioclase at Flakaliden and epidote  
479 at Asa. In line with our second hypothesis, the overestimation of calcic plagioclase in  $M_{A2M-site}$  at Asa at the expense

480 of epidote and amphibole (Casetou-Gustafson et al., 2018) was directly reflected in the significant discrepancy  
481 and overestimated weathering rates of Ca by  $W_{A2M\text{-site}}$  compared to  $W_{XRPD}$  (Fig. 5, and 1a). This discrepancy was  
482 due to differences between  $W_{A2M\text{-site}}$  and  $W_{XRPD}$  in the mineral stoichiometry of calcic plagioclases, and not in  
483 geochemistry, as the same geochemical analyses were also used for  $W_{A2M\text{-reg}}$ .

484

485 At Flakaliden, A2M based on site-specific mineralogy overestimated epidote at the expense of amphibole  
486 (Casetou-Gustafson et al., 2018), leading to an underestimation of Ca weathering rates from amphibole compared  
487 to epidote (Fig. 5). On the other hand, at Asa, it was the regional mineralogy input to A2M that resulted in  
488 overestimated amounts of epidote at the expense of dioctahedral vermiculite and amphibole, and this bias was  
489 directly reflected in the underestimated release of Ca from amphibole in  $W_{A2M\text{-reg}}$ . Conversely, the relatively small  
490 and non-significant discrepancies of Ca release by  $W_{A2M\text{-site}}$  at Flakaliden and by  $W_{A2M\text{-reg}}$  at Asa did not depend  
491 on a high precision in estimating the contribution from different minerals, since the precision was actually low. In  
492 these cases, the good fits seem to be simply coincidental. Owing to differences in dissolution rates, Ca-bearing  
493 minerals tend to compensate each other in terms of the total weathering rate that is calculated. This compensatory  
494 effect is perhaps the reason why by coincidence, both  $W_{A2M\text{-reg}}$  and  $W_{A2M\text{-site}}$  discrepancies for Ca diverge in  
495 different directions at Asa compared to Flakaliden.

496

497 Another source of uncertainty associated with the release of Ca is the role of minerals with high dissolution rates  
498 that occur in low abundance, for example apatite, pyroxene and calcite. Apatite was included in  $M_{A2M}$ , but if present  
499 in the soils studied was below the detection limit of 1 wt.% in the XRPD analyses as were pyroxene and calcite  
500 (Casetou-Gustafson et al., 2018). Additionally, the assumption made in the A2M calculations that all P determined  
501 in the geochemical analyses is allocated to apatite will likely overestimate the abundance of this mineral since soil  
502 P can also occur bound to Fe and Al oxides and soil organic matter in acidic mineral soils (Weil and Brady, 2016).  
503 The relatively high abundance of paracrystalline Fe-oxyhydroxide and Al-containing allophane and imogolite at  
504 Flakaliden indicates that this could be the case, at least at Flakaliden.

505

506 Regarding pyroxene, XRPD might also have failed to detect and quantify pyroxene due to low abundance at  
507 Flakaliden (Casetou-Gustafson et al., 2018). Analytical limitations of XRPD would thus imply that  $W_{XRPD}$  of Ca  
508 might be underestimated at Flakaliden and Asa. However, in the absence of XRPD detection it is also possible that  
509  $M_{A2M\text{-reg}}$  overestimated the pyroxene contents at Flakaliden. Thus, apatite and pyroxene added relatively large  
510 uncertainties to the weathering estimates of Ca at Flakaliden due to the fact that they have a low abundance in  
511 combination with very high dissolution rates. In terms of other reactive trace mineral phases, White et al. (1996,  
512 2017) has highlighted the importance of small amounts of calcite in intact granitoid rocks and its significance for  
513 Ca found in watershed studies. They also noted that in laboratory leaching experiments on the rocks they studied,  
514 reactive calcite became exhausted after just 1.5 years. Given the trace concentrations involved and the high  
515 solubility of calcite it is doubtful that calcite is or has been of any long-lived significance in the soil profiles  
516 studied, even though they are derived largely from rocks of granitic composition. Although, the results of White  
517 et al. (1996, 2017) do suggest that calcite present in the in-situ granitoid rocks underlying the soils may well  
518 contribute to Ca export from the catchment. Additionally, the overestimation of the slowly weatherable mineral  
519 illite by  $M_{A2M\text{-reg}}$  (Casetou-Gustafson et al., 2018) resulted in an underestimation of Ca release by  $W_{A2M\text{-reg}}$  at

520 Flakaliden, since less Ca was allocated to the more weatherable minerals. Although, it should also be noted  
521 parenthetically that Ca can only occur as an exchangeable cation in illite, it is not an element that occurs as part of  
522 the illite crystal structure, such that the ‘illite’ composition used in PROFILE is in need of some revision.

523 **4.3.3 Magnesium release rates**

524 At both study sites, a large number of Mg-containing minerals contributed to the release of Mg, but amphibole  
525 was the predominant mineral according to  $W_{XRPD}$  and  $W_{A2M\text{-site}}$ . The only significant discrepancy in Mg release  
526 rates was revealed for  $W_{A2M\text{-site}}$  at Asa, which resulted in an overestimation by 41 %. This overestimation was an  
527 effect of underestimated contribution from amphibole in combination with overestimated contributions from  
528 hydrobiotite and trioctahedral mica. This result for Asa supported our second hypothesis. At Flakaliden,  $W_{A2M\text{-site}}$   
529 produced the same shift in the contribution of Mg by minerals, but the net effect was a very small and non-  
530 significant discrepancy to  $W_{XRPD}$ . As was noted for Ca, the different outcomes of using site-specific mineralogies  
531 at Asa and Flakaliden has no systematic underlying pattern.

532 Using PROFILE based on regional mineralogy resulted in surprisingly low and non-significant discrepancies in  
533 Mg release rate, despite both the qualitative and quantitative mineralogies being very different from XRPD,  
534 particularly at Flakaliden. For example, both pyroxene and illite were included in  $M_{A2M\text{-reg}}$ , but not in  $M_{XRPD}$ . Thus,  
535 at Flakaliden, the overestimation of illite in  $M_{A2M\text{-reg}}$  caused an underestimation of Mg release rates comparable to  
536 the underestimation of Ca release rates.

537 **4.3.4 Potassium release rates**

538 Weathering of K-feldspar was the most important source of K release by PROFILE regardless of the different  
539 types of mineralogy input. Casetou-Gustafson et al. (2018) showed a strong negative correlation between  $M_{A2M\text{-reg}}$   
540 and  $M_{XRPD}$  for two of the major K-bearing minerals observed at both study sites, i.e., illite (or dioctahedral mica,  
541 muscovite) and K-feldspar. Contrary to our second hypothesis, the results of the present study demonstrate that  
542 over-or underestimation of  $W_{A2M\text{-reg}}$  compared to  $W_{XRPD}$  cannot be explained by significant negative correlation of  
543 illite and K-feldspar in  $M_{A2M\text{-reg}}$ . However, this is likely related to the fact that illite and K-feldspar have the lowest  
544 and also quite similar dissolution rates among minerals included in PROFILE (i.e. the highest dissolution  
545 coefficients, Table 3). Although very different inputs in relation to K bearing minerals produced very similar  
546 outputs, we note that this appears contradictory to differences in the behaviour of K-feldspars and K-micas as  
547 sources of K via weathering to plants as reviewed for example by Thompson and Ukrainczyk (2002). Additionally  
548 we note that Hodson et al. (1997) compared reaction rate constants for different minerals from Sverdrup et al.  
549 (1990) with their own calculations and the discrepancies were relatively large for some minerals, e.g. muscovite.

550 **5. Concluding remarks**

- 551 • Based on comparing the full solution span of normative mineralogy from the A2M program to measured  
552 reference mineralogy from XRPD overall similar weathering rates were generated by the different  
553 mineralogical inputs to the PROFILE model. However, the underlying contributions from different  
554 minerals to the overall rates differed markedly. Although the similarity of overall rates lends some support  
555 to the use of normative mineralogy as input to weathering models, the details of the comparison reveal  
556 potential short-comings and room for improvements in the use of normative mineralogies.

- Compared with regional mineralogy, weathering rates based on site-specific mineralogy were more comparable to the reference rates generated from XRPD mineralogy, in line with hypothesis 1, at one of the study sites (Flakaliden), but not at the other (Asa). Thus, although intuitively the more detailed site specific quantitative mineralogy data might be expected to give more comparable results, this is not supported by this study.
- For Ca and Mg the differences between weathering rates based on different mineralogies could be explained by differences in the content (modelled or actual) of some specific Ca- and Mg-bearing minerals, e.g. amphibole, apatite, pyroxene, calcite and illite. Improving certainty in relation to presence versus absence of some of these minerals and if present accurate quantification at low levels would reduce weathering rate calculation uncertainties.
- High uncertainties in mineralogy, due for example to different A2M assumptions, had surprisingly low effect on the weathering from Na- and K-bearing minerals. This can be explained by the fact that the weathering rate constants for the minerals involved, e.g. the plagioclase feldspars and K-feldspar and dioctahedral micas, are similar in PROFILE such that they compensate each other in the overall weathering rate outputs for these elements, a situation that is unlikely to reflect reality.
- For more in-depth analysis of the uncertainties in weathering rates caused by mineralogy, the rate coefficients of minerals should be revisited and their uncertainties assessed. A revision of rate constants could lead to results more in line with hypothesis 1.

## 6. Authors contribution

Authors contributed to the study as in the following: S. Casetou-Gustafson: study design, data treatment, PROFILE model analyses, interpretation and writing. C. Akselsson: study design, PROFILE model development, interpretation and writing. B.A. Olsson: study design, interpretation and writing. S. Hillier: interpretation and writing.

## 7. Acknowledgements

Financial support from The Swedish research Council for Environment, Agricultural Sciences and Spatial Planning (212-2011-1691) (FORMAS) (Strong Research Environment, QWARTS) and the Swedish Energy Agency (p36151-1). Stephen Hillier acknowledges support of the Scottish Government's Rural and Environment Science and Analytical Services Division (RESAS). We thank Salim Belyazid for his contribution to the design of the study. We also acknowledge the constructive comments of the anonymous reviewers which helped to improve the manuscript.

726   **Table 3** Mineral dissolution rate coefficients ( $\text{kmol}_c \text{ m}^{-2} \text{ s}^{-1}$ ) used in PROFILE for the reactions with  $\text{H}^+$ ,  $\text{H}_2\text{O}$ ,  
 727    $\text{CO}_2$  and organic ligands ( $\text{R}^-$ ) (Warfvinge and Sverdrup, 1995).

| Mineral              | pkH  | pkH <sub>2</sub> O | pkCO <sub>2</sub> | pKR  |
|----------------------|------|--------------------|-------------------|------|
| Pyroxene             | 12.3 | 17.5               | 15.8              | 14.4 |
| Apatite              | 12.8 | 15.8               | 15.8              | 19.5 |
| Hornblende           | 13.3 | 16.3               | 15.9              | 14.4 |
| Epidote              | 14   | 17.2               | 16.2              | 14.4 |
| Plagioclase          | 14.6 | 16.8               | 15.9              | 14.7 |
| K-Feldspar           | 14.7 | 17.2               | 16.8              | 15   |
| Biotite              | 14.8 | 16.7               | 15.8              | 14.8 |
| Chlorite             | 14.8 | 17                 | 16.2              | 15   |
| Vermiculite          | 14.8 | 17.2               | 16.2              | 15.2 |
| Muscovite and Illite | 15.2 | 17.5               | 16.5              | 15.3 |

745 **Figure captions**

746 **Figure 1.** The first scenario for describing the effect of mineralogy on weathering rates in the upper mineral soil  
747 for a specific soil profile (a) happens when the PROFILE weathering rate based on XRPD (reference weathering  
748 rates) is not contained in the weathering range produced using PROFILE in combination with the full A2M  
749 solution space. There are two possible explanations of why a significant discrepancy introduces an uncertainty  
750 range, i.e. (1) due to uncertainties related to the mineralogical A2M input and (2) due to uncertainties related to  
751 the limitation of the XRPD method itself (i.e. detection limit). The second scenario (b) occurs when the reference  
752 weathering rate is contained in the full A2M weathering span. In this case we speak of ‘non-significant  
753 discrepancies’.

754 **Figure 2.** Comparison of PROFILE weathering rates of base cations ( $\text{mmol}_c \text{ m}^{-2} \text{ yr}^{-1}$ ) at Asa (a) and Flakaliden  
755 (b) sites in the 0–50 cm horizon based on XRPD mineralogy (vertical dashed lines) with PROFILE weathering  
756 rates based on one thousand random regional A2M mineralogies versus one thousand random site-specific A2M  
757 mineralogies. Data presented are from four different soil profiles per site. Regional graph for soil profile 10B at  
758 Flakaliden is missing since A2M did not calculate 1000 solutions for soil layer 20-30, due to “Non-positive  
759 solution”.

760 **Figure 3.** Root-mean square error (RMSE) of average PROFILE weathering rates ( $\text{mmol}_c \text{ m}^{-2} \text{ yr}^{-1}$ ) of one  
761 thousand A2M mineralogies per soil layer, compared to weathering rates based on XRPD mineralogy per soil  
762 layer. Comparisons are based on the total weathering per element (A) and on the sum of mineral contributions to  
763 total weathering per element (B). RMSE describes the prediction accuracy for a single soil layer.

764 **Figure 4.** Comparison of PROFILE weathering rates based on XRPD mineralogy ( $\text{mmol}_c \text{ m}^{-2} \text{ yr}^{-1}$ ) with  
765 PROFILE weathering rates based on regional A2M mineralogy (upper figures) versus site-specific mineralogy  
766 (lower figures). Each data point represents a mean of one thousand PROFILE weathering rates for a specific soil  
767 depth of one of 4 soil profiles per site.

768 **Figure 5.** Comparison of sums of PROFILE base cation weathering rates for different minerals in the upper  
769 mineral soil (0–50 cm) based on XRPD mineralogy and the average PROFILE base cation weathering rate (i.e.  
770 based on one thousands input A2M mineralogies per mineral) according to the two normative mineralogical  
771 methods and for each study site (i.e. Asa site-specific, Flakaliden site-specific, Asa regional, Flakaliden  
772 regional). For  $W_{\text{A2M}}$ , relative error (% of  $W_{\text{XRPD}}$  estimate) are given at the end of each bar to illustrate the  
773 average deviation of  $W_{\text{A2M}}$  and  $W_{\text{XRPD}}$  in the upper mineral soil. \*=significant discrepancy as defined in section  
774 2.7. Vrm1=Trioctahedral vermiculite; Vrm2=Dioctahdreal vermiculite. Information on chemical compositions of  
775 minerals are given in Table S5 and S6.
