20 **Abstract**

21 This study deals with 16S rDNA identified bacteria, *Lysinibacillus sphaericus* (71A), *Raoultella planticola*  
22 (VIP), and *Streptomyces pluricolorescens* (EM4) capable of precipitating CaCO<sub>3</sub> through a nitrate reduction  
23 aerobically and anaerobically. The produced CaCO<sub>3</sub> crystals were analyzed using XRD, EDX, and SEM. The  
24 results showed that the carbonatogenic bacteria served as nucleation sites for CaCO<sub>3</sub> precipitation with distinct  
25 variation in polymorph and morphology; reflecting strain-specific property. Notably, the amount of precipitated  
26 CaCO<sub>3</sub> recorded 3.27 (aerobic), 1.55 (anaerobic), 4.15 (aerobic), 3.75 (aerobic) and 1.87 (anaerobic) g/100 mL of  
27 strains 71A, EM4 and VIP, respectively, for 240h of incubation. The study of changes in media chemistry during  
28 carbonatogenesis process revealed positive correlation between bacterial growth, nitrate reductase activity, pH,  
29 EC, amount of deposited CaCO<sub>3</sub> and NO<sub>3</sub><sup>-</sup> consumption. Therefore, the applications of these bacterial strains,  
30 which employed for the first time in carbonatogenesis process, are promising in the environmental, biomedical  
31 and civil engineering fields.

32 **Key words:** *Streptomysetes*, CaCO<sub>3</sub> biodeposition, carbonatogenesis process, nitrate reduction,  
33 biocementation.

## 43 1. Introduction

44 Biom mineralization is a process of inorganic mineral deposition by living organisms, which occurs  
45 naturally at a slow rate over geological times. Microorganisms mediate the biom mineralization process  
46 through a sequence of biochemical activities and physiological pathways, which alter the chemical  
47 environment and ultimately lead to mineral precipitation (**Chaparro-Acuña et al., 2018**), by two main  
48 different mechanisms; biologically controlled mineralization (BCM) and biologically induced  
49 mineralization (BIM) (**Ghosh et al., 2019, Wei et al., 2015; Anbu, et al., 2016**).

50 Interestingly, Microbial induced calcium carbonate precipitation (MICCP) which also called  
51 carbonatogenesis attracted a considerable attention in various biotechnological applications.  
52 Carbonatogenesis is an eco-friendly and cost-effective technology that can be applied to remediate  
53 various environmental pollution originated from anthropogenic activities (**Rodriguez-Navarro et al.,**  
54 **2012**). As referred by **Chaparro-Acuña et al., (2018)**. It enhances water quality in water softening  
55 process, which subsequently participates in solving water crisis problem. On industrial level, calcium  
56 carbonates have been widely used as viscosity modifier in plastics, rubber, inks, paint, paper and  
57 pigment products (**Anbu et al., 2016**). For medical and therapeutic sectors, it has been utilized in drug  
58 delivery and tissue engineering (**Poelvoorde, 2017**). Recently, microbial  $\text{CaCO}_3$  paved the way for  
59 new subdiscipline in biotechnology, which is construction microbial biotechnology, including  
60 biocrusting, and biocementation (**O'Donnell et al., 2019**).

61 Naturally, calcium carbonate occurs on earth's surface, and contributes mainly in geochemical reservoir  
62 for carbon (**Hu et al., 2012**). It exists in various polymorphs with distinct characteristics, including  
63 vaterite (the most thermodynamically unstable and the highest solubility spherical like), aragonite (the  
64 densest and thermodynamically unstable needle like), calcite (the most stable rhombic), two hydrated  
65 crystalline phases, monohydrocalcite, ikaite and amorphous phases (**Sevcik et al., 2018**). The  
66 metastable phases can be easily recrystallized to stable calcite phase (**Han et al., 2017**). As reported in  
67 extensive studies (**Ersan et al., 2015, Ghosh et al., 2019**), different microorganisms precipitated  
68 different types of  $\text{CaCO}_3$ .

69 The calcifying microorganisms stimulate  $\text{CaCO}_3$  precipitation via two fundamental mechanisms either  
70 autotrophic or heterotrophic (**Singh, 2019**); which seems to be more abundant. Photosynthetic  
71 microorganisms fix  $\text{CO}_2$  and induce carbonate precipitation autotrophically (**Richardson et al., 2014**).  
72 Conversely, three main categories of microorganisms induce biocalcification process heterotrophically.  
73 The first category catalyzes the reduction of sulphate by sulphate reducing bacteria (SRB) (**Lin et al.,**  
74 **2018**). The second category comprises microorganisms, which participate in nitrogen cycle by one of  
75 the following means: A)- oxidative deamination of amino acids, B)- nitrate reduction C)- urea  
76 hydrolysis (**Richardson et al., 2014**). The third category promotes the reversible conversion of  $\text{CO}_2$  to  
77 bicarbonate through carbonic anhydrase enzyme (**Zhu and Dittrich 2016**).

78 Remarkably, the majority of studies concerned with calcification technology focused on ureolysis  
79 processes and few researches were performed on nitrate dissimilation metabolism (**Zhu and Dittrich**  
80 **2016**). Nonetheless, ureolysis processes exhibited several limitations, namely; the byproduct of urea  
81 hydrolysis (ammonia or ammonium), which is potentially hazardous, requires removal later on by  
82 another stage (**O'Donnell et al., 2019**). Moreover, the using of aerobic urolytic bacteria *in situ* will  
83 result in calcite disintegration due to oxygen shortage and changing in pH surrounding to bacteria,  
84 which eventually lead to insufficient applications (**Thirumalai, 2015**). Interestingly, carbonatogenesis  
85 via dissimilatory nitrate reduction deemed as remarkable alternative mechanism that can overcome the  
86 drawbacks of ureolysis. Where, nitrate dissimilatory microorganisms are more prevalent in the  
87 subsurface and display flexibility in their growth strategy; they are able to utilize low  $\text{NO}_3^-$   
88 concentrations under anoxic conditions and without formation of harmful or toxic byproducts. Besides,  
89 denitrification is thermodynamically more favorable than ureolysis. As refereed by **Ersan et al., 2015**,  
90 the change in standard Gibbs energy for denitrification is  $-785 \text{ kJ/mol}$  acetate, while it was estimated to  
91 be  $-27 \text{ kJ/mol}$  acetate for ureolysis. Furthermore, the carbonate yield generated by denitrification  
92 process is higher than ureolysis.

93 Accordingly, the present study aimed to determine the carbonate precipitation efficiency of  
94 heterotrophic nitrate dissimilating bacteria under both aerobic and anaerobic conditions. The selected

95 nitrate reducing-bacteria under study were isolated from Egyptian non-calcareous habitats and identified  
96 by 16S rDNA gene sequencing. The substantial part of this study focused on characterization of  $\text{CaCO}_3$   
97 precipitated by each strain under oxic and anoxic conditions, which will check the suitability of each  
98  $\text{CaCO}_3$  crystals considering their prospective application according to mineralogy and morphology.  
99 Subsequently, different criteria such as bacterial count, nitrate reductase (NR) activity, pH, deposited  
100  $\text{CaCO}_3$  amount,  $\text{NO}_3^-$  concentration,  $\text{NO}_2^-$  concentration and electrical conductivity (EC) were analyzed.  
101 As far as the authors know, it is the first report of carbonatogenesis process through nitrate reduction  
102 under aerobic and anaerobic conditions.

## 103 2. Materials and Methods

### 104 2.1. Sampling, screening and selection of nitrate-reducing bacteria

105 Sediment samples were collected from non-calcareous Egyptian sites; Naba Alhamra at Wadi Elnatron  
106 (Al-Beheira governorate), Karon Lake (Al-Fayoum governorate) and Mariot Lake (Alexandria  
107 governorate). Directly after sampling, isolation and screening of bacteria for nitrate reduction were  
108 performed. Initially, 1 g of fine powdered homogenized samples were serially diluted in 0.85 % saline,  
109 and then plated on denitrifying media containing bromothymol blue and incubated aerobically (Lv et  
110 al., 2017). The bacterial isolates that reduced nitrate aerobically were picked up and re-examined for  
111 nitrate reduction under anaerobic conditions as described by Zaki et al. (2019). Out of 17 nitrate  
112 reducing-bacteria, three isolates, designated as 71A, VIP and EM4 were selected based on their nitrate  
113 reduction capabilities. Generally, nitrate reductase (NR) assay performed using spectrophotometric  
114 measurement of nitrite concentration at 540 nm. This was based on diazo-coupling method with  
115 Griess reagents (0.2 % Naphthyl ethylenediamine and 2% Sulfanilamide in 5% phosphoric acid).  
116 Nitrite generated from nitrate in presence of 40 mM of an artificial electron donor dithionite  
117 benzyle viologen. One unit of NR activity corresponds to the amount of enzyme that catalyzes  
118 the formation of  $1\mu\text{mol}$  of nitrite per minute or  $1\mu\text{mol}$  of nitrate reduced per minute under  
119 standard assay conditions (Zaki et al., 2019).

### 120 2.2. Molecular identification of selected isolates

121 The selected isolates were identified using 16S rDNA sequencing. The bacterial genomic DNAs of the  
122 selected isolates were extracted from overnight pure cultures and 16S rDNA genes were PCR amplified,  
123 purified and sequenced as described elsewhere (Vashisht et al., 2018). The phylogenetic affiliation was  
124 inquired by applying BLAST analysis to determine the similarities with their available GenBank  
125 database sequences. Their generated sequences were submitted to the GenBank to obtain corresponding  
126 accession numbers. For multiple alignment and phylogenetic tree construction, the software package  
127 MEGA- 6 was employed.

### 128 2.3. CaCO<sub>3</sub> precipitation and crystals collection

129 The capability of selected isolates for CaCO<sub>3</sub> precipitation through nitrate reduction process was  
130 assessed in liquid broth method at flask level. About 250 µL of bacterial cultures (1.8 x 10<sup>6</sup> CFU/mL)  
131 were inoculated in 200 ml CaCO<sub>3</sub> precipitation media (CCP) which composed of M9 media  
132 supplemented with (g/L): sodium acetate (10) and Ca (NO<sub>3</sub>)<sub>2</sub>·4H<sub>2</sub>O (15) at pH 7.0 ± 2.2 (Ersan et al.,  
133 2015). The flasks were incubated aerobically in an orbital shaker at 150 rpm and anaerobically as  
134 stated by Zaki et al., (2019). The inoculated flasks were incubated at 30°C for 10 days. An abiotic  
135 negative control consisted of un-inoculated media was run in parallel. At the end of the experiment, the  
136 whole cultures were centrifuged at 10.000g for 20 min and washed successive times by distilled water  
137 and ethanol to eliminate any nutritive solution. The air-dried minerals were weighted to estimate the  
138 amount of precipitated CaCO<sub>3</sub> and subsequently subjected to mineralogical studies (Vashisht et al.,  
139 2018).

### 140 2.4. Mineralogical and morphological analysis

141 The mineralogical analysis of the dried precipitated CaCO<sub>3</sub> was established with X-ray diffraction  
142 (XRD), Energy dispersive X-ray spectroscopy (EDX) and scanning electronic microscopy (SEM). The  
143 mineral phase of precipitated CaCO<sub>3</sub> was identified using X-ray diffractometer ((Bruker MeaSrv D2-  
144 208219, Germany-Central Lab, Faculty of science, Alexandria University) that operating with Cu  
145 K $\alpha$  radiation ( $\lambda = 0.15406$  nm) generated at 30 kV and 30 mA with scan rate of 2°/min for 2 $\theta$  values

146 over a wide range of Bragg angles  $10^\circ \leq 2\theta \leq 80$ . The microchemical sample analysis was carried out  
147 using EDX analyzer combined with SEM (JEOL JSM 6360LA, Japan). The morphological  
148 characteristics of bacterial  $\text{CaCO}_3$  was observed using SEM (JEOL JSM 6360LA, Japan – Advanced  
149 Technologies and New Materials Research Institute (ATNMRI) SRTA-City) at an accelerating  
150 voltage of 20 kV (Silva-Castro et al., 2015).

## 151 2.5. Study of the parameters associated with $\text{CaCO}_3$ precipitation

152 The correlation between  $\text{CaCO}_3$  formation and the parametric changes in culture media during different  
153 growth phases of all strains under study were investigated. The parameters; bacterial count, NR activity,  
154 concentrations of  $\text{NO}_3^-$ ,  $\text{NO}_2^-$ , pH, electrical conductivity (EC), and weight of precipitated  $\text{CaCO}_3$  were  
155 screened at constant time intervals. Strains were inoculated on the media, which were reported formerly  
156 and incubated at  $30^\circ\text{C}$  both aerobically and anaerobically for 10 days. At each time interval (6 h), about  
157 15 mL aliquot of the culture was drawn and subjected for analysis. Pour plate method was applied for  
158 assessing the bacterial count (CFU/ mL) on nutrient agar and incubated overnight at  $30^\circ\text{C}$ . The  
159 precipitated  $\text{CaCO}_3$  was collected by centrifugation at 10.000 g for 15 min, washed with sterile distilled  
160 water, air dried and weighed. The supernatant was used to determine the rest of parameters, where, pH  
161 values were measured using a pH indicator (PB-10, Sartorius AG), while EC measured using electric  
162 conductivity meter (JENWAY- 4510). The concentrations of  $\text{NO}_3^-$  and  $\text{NO}_2^-$ , were measured according  
163 to the procedure followed by APHA, (1999).

## 164 3. Results and Discussion:

### 165 3.1. Isolation and identification of bacteria

166 Among 17-screened bacterial isolates, three of them 71A, VIP and EM4 were selected based on their  
167 high NR activity. Then isolates were subjected for taxonomic identification and examination of  
168 carbonatogenesis process. The partial 16S rDNA sequences of 1127, 1025 and 800 bp of isolates 71A,  
169 VIP and EM4 exhibited 98.4, 97.2 and 99.8% DNA similarities with *Lysinibacillus sphaericus*,  
170 *Raoultella planticola* and *Streptomyces pluricolorescens*, respectively. Their 16S rDNA sequences were

171 deposited in the GenBank under accession numbers MK936472 (71A), MK551748 (VIP) and  
172 KY964509 (EM4). Strain 71A is belonging to the phylum Firmicutes and family Bacillaceae. Whereas,  
173 the taxonomic affiliation of VIP and EM4 are belonging to phylum Proteobacteria, family  
174 Enterobacteriaceae and phylum Actinobacteria, family Actinomycetaceae, respectively. As pointed out  
175 by **Silva-Castro et al., (2015)**, members of Firmicutes phylum are the most predominant in MICCP  
176 process through ureolysis. Besides, **Talaiekhosani et al., (2014)** referred to the calcification potency of  
177 ureolytic *Proteus vulgaris* in concrete self-healing, which grouped in family Enterobacteriaceae.  
178 Additionally, some genera affiliated to Actinobacteria deposited CaCO<sub>3</sub> based on metabolizing  
179 nitrogenated organic substrates such as peptone and yeast extract (**Torres et al., 2013**). The  
180 phylogenetic tree of the selected strains was constructed by the Neighbour-joining (NJ) method as  
181 indicated in Fig. 1.

### 182 3.2. Nitrate Reductase activity (NR)

183 Actually, among 17 screened isolates, *L. sphaericus* (71A), *R. planticola* (VIP), and *S. pluricologrescens*  
184 (EM4) showed the maximum NR activity, after 24 h of incubation exhibiting 449, 534 and 768 μmole/  
185 min/ml, respectively under aerobic conditions. However, under anaerobic conditions and on the 1<sup>st</sup> day  
186 of incubation, NR activity was 189 and 426 μmole/min/ml with strains 71A and VIP, respectively. In  
187 general, the NR activity of both strains was increased along with the incubation time as mentioned later  
188 on. On the other hand, strain EM4 did not show NR activity anaerobically, while it exhibited the highest  
189 NR activity aerobically. Therefore, it was selected. Our knowledge, there were no previous studies  
190 reported *Streptomyces* species in carbonatogenesis process through nitrate dissimilation pathway.

### 191 3.3. CaCO<sub>3</sub> biodeposition

192 Despite of almost preceding literature emphasized that the successes in isolation of CCP organisms are  
193 in particular based on the selection of sampling sites (calcareous and cementitious); the existing  
194 investigation did not comply with this rule. Despite, all of the isolates were isolated from non-  
195 calcareous sites; they possessed the specified mechanism, which allows CaCO<sub>3</sub> biodeposition

196 (Montano-Salazar et al., 2017). The selected strains that precipitated crystals in CCP medium at 30°C  
197 under aerobic and anaerobic conditions exhibited different appearance, which includes crystal size,  
198 texture and color Fig. 2. Conversely, clear solution without any precipitates was observed in the abiotic  
199 uninoculated experiment (control), implying the ability of active strains to modify the chemistry of  
200 culture media and creating the proper microenvironments favoring CaCO<sub>3</sub> precipitation. Obviously,  
201 large beige or buff color and irregular crystals were appeared in anaerobic cultures, whereas fine white  
202 powder was formed in aerobic cultures of strains 71A and VIP, while, strain EM4 culture showed  
203 yellowish- brown aggregated pellets. Interestingly, the inter-species differences in crystallization  
204 patterns, colors, textures and forms were noticed previously by **Montano-Salazar et al., (2017)**, where,  
205 *Rhodococcus qingshengii* M101, *Arthrobacter crystallopoietes* and *Psychrobacillus psychrodurans*  
206 showed spherical brown, irregular yellowish and irregular white/beige aggregated crystals of CaCO<sub>3</sub>,  
207 respectively.

208 To study the involvement of nitrate dissimilation in CaCO<sub>3</sub> formation, the changes in the chemistry of  
209 media was monitored. Generally, a positive correlation was observed between the amount of  
210 precipitated CaCO<sub>3</sub> with bacterial growth that was synchronized with NR activity, pH, EC, NO<sub>3</sub><sup>-</sup>/NO<sub>2</sub><sup>-</sup>  
211 reduction Fig. 3. The aerobic growth resulted in the higher bacterial count, NR activity and eventually  
212 higher amount of CaCO<sub>3</sub>. Such is plausible due to the availability of higher redox potential in presence  
213 of oxygen (+818 mV), which supports rapid energy generation, higher metabolic activity and hence  
214 higher reproduction rate (**Ilbert and Bonnefoy, 2013**). Evidently, the cell number increased rapidly and  
215 reached to the maximum between 90h and 120h depending on the strain, thereafter it decreased slowly  
216 and steadily until the end of the experiment (240h). Remarkably, upon 120h of aerobic incubation,  
217 about 4.5x 10<sup>8</sup> CFU/mL of strain 71A with maximum NR activity (779 μmol/min/mL) completely  
218 reduced NO<sub>3</sub><sup>-</sup> and uplifted pH from 7.01 to 8.53. In the same extent, the aerobic culture of strain VIP  
219 removed NO<sub>3</sub><sup>-</sup> completely and elevating the initial pH from 7.01 to 8.91 at 90h by the activity of 6.65 x  
220 10<sup>8</sup> CFU/ml, which exhibiting 862 μmol/min/mL of NR activity. Interestingly, strain EM4 (6.6 x 10<sup>7</sup>  
221 CFU/ ml) displayed the highest NR activity with 1292 μmol/min/mL and increasing pH to 9.51 with  
222 complete NO<sub>3</sub><sup>-</sup> reduction at 102h of incubation.

223 In comparison, the anaerobic cultures ( $9.7 \times 10^6$  and  $7.1 \times 10^7$  CFU/ mL) of strains 71A and VIP  
224 eliminated  $\text{NO}_3^-$  by means of 180 and 66h, respectively. However, NR activity and pH were recorded  
225 372 and 661  $\mu\text{mol}/\text{min}/\text{mL}$  and 8.8 and 9.7 for 71A and VIP, respectively. In addition, a complete  
226 denitrification process was achieved upon continued anaerobic incubation. Obviously, NR activity was  
227 expressed aerobically even after the complete depletion of  $\text{NO}_3^-$  and in the presence of  $\text{NO}_2^-$ , whereas,  
228 under anaerobic conditions, it induced only in the presence of  $\text{NO}_3^-$ . That could be assigned to the  
229 physiological role differences of NRs under different aeration conditions. Remarkably, membrane-  
230 bound NR is induced under the absolute absence of oxygen and mainly involves in anaerobic nitrate  
231 respiration, for production of the electrochemical proton gradient and generation of ATP (**Zaki et al.,**  
232 **2019**). On the other hand, periplasmic NR is unaffected by oxygen level or C and N balance; it  
233 maintains redox homeostasis by dissipating excess reductant during aerobic growth and scavenging  
234 toxic concentrations of nitrate and nitrite as pointed out by **Li et al., (2012)**. Thus, NR activity was  
235 observed along with aerobic incubation process. Furthermore, the availability of more bacterial cell  
236 number enables more nucleation sites, which ultimately precipitate more carbonate crystals  
237 (**Rodriguez-Navarro et al.2007**). Virtually, the amount of  $\text{CaCO}_3$  precipitates kept increasing  
238 gradually during the mineralization process and recorded in  $\text{g}/100 \text{ mL}$ , 3.27 and 1.55 for strain 71A  
239 (aerobic and anaerobic), 3.75 and 1.87 for strain VIP (aerobic and anaerobic) and 4.15 for strain EM4  
240 (aerobic only), by 240h of incubation. On the other hand, **Gomaa, (2018)** stated that *Micrococcus* sp.  
241 induced 10.80 mg/ml of  $\text{CaCO}_3$ . Additionally, **Kaur et al., (2013)** documented that within three weeks  
242 of incubation, *B. megaterium*, *B. subtilis*, *B. thuringiensis*, *B. cereus* and *L. fusiformis* produced 187,  
243 178, 167, 156 and 152 mg/100 ml of  $\text{CaCO}_3$  via ureolysis pathway, which make results of the current  
244 study characteristic. Regarding the incubation time, a similar period for the  $\text{CaCO}_3$  biodeposition was  
245 observed by **Rodriguez-Navarro et al. (2007)** for *Myxococcus xanthus*.

246 Consistent with the bacterial count, NR activity and pH, a linear progressive increase in EC was  
247 noticed. That could be ascribed to the elevation of medium conductivity ( $\text{mS}/\text{cm}/\text{min}$ ) by the action of  
248 charged ions such as  $\text{NO}_2^-$ ,  $\text{N}_2\text{O}^-$ ,  $\text{NO}^-$ ,  $\text{Ca}^{2+}$  and  $\text{CO}_3^{2-}$  ions generated by microbial activity on non-  
249 conductive substrates (sodium acetate and  $\text{Ca}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$ ). It is worth mention that the conductimetric

250 method is mainly used in evaluation of ureolysis process to follow the generation of ionic products from  
251 non-ionic substrates and consequently give insight on the microbial activity and mineralization  
252 tendency. Besides, it was used to control the kinetics of nucleation and crystal growth of carbonate  
253 precipitation process in the presence of exopolymer as referred by **Szcześ et al., (2018)**. Near the end of  
254 the experiment, a slight decline or stability state was observed by the almost of examined parameters for  
255 all bacterial strains both aerobically and anaerobically. That could be attributed either to entrance of the  
256 cells in stationary phase, where no more increase in cell number as a result of nutrient depletion and  
257 subsequently no more  $\text{CaCO}_3$  precipitation, or fossilization of the cells within  $\text{CaCO}_3$  crystals. The  
258 latter case caused mineralization of bacterial cell wall, which subsequently inhibited nutrient exchange  
259 with surrounding environment and eventually cell death as recorded by **Silva-Castro et al., (2015)**.

#### 260 **3.4. $\text{CaCO}_3$ crystal analysis**

261 XRD, EDX, and SEM techniques were employed to characterize the deposited  $\text{CaCO}_3$  crystals. The  
262 nature of crystals, crystallographic identity and phase purity of inorganic compounds were determined  
263 using XRD. The characteristic signature peaks of calcite at  $2\theta$  values of 23.13, 29.50, 36.04, 39.51,  
264 43.31, 47.51, 48.65, 56.71, 57.50, 60.81, 63.22, 64.42, and 65.57, respectively correlated with lattice  
265 (hkl) indices of (012), (104) (110), (113), (202), (024), (116), (211), (122), (214), (125), (300) and  
266 (0012) were identified in strain 71A precipitated samples under both incubation conditions. On the other  
267 hand, the XRD spectrum of strain VIP samples recorded calcite and vaterite under aerobic and  
268 anaerobic conditions, respectively Fig. 4. In regards to examined sample of strain EM4, the relative  
269 intensities and the reflection peak positions at 20.93, 24.81, 27.13, 32.75, 39.82, 42.66, 43.13, 49.85,  
270 51.13, 55.75, 60.36, 62.54 and 65.38, which corresponds to crystallographic planes of (002), (100),  
271 (101), (102), (103), (004), (110), (104), (200), (202), (105), (114) and (006), respectively, confirms the  
272 presence of vaterite Fig. 4 (D & E). The diffraction peaks of calcite and vaterite match with those  
273 of the standard spectrum JCPDS, No. 02-0629 and JCPDS, No. 72-0506, respectively  
274 (**Svenskaya et al., 2017**). Generally, the diffractograms of all examined samples appeared sharp,

275 clearly distinguishable and broad, which indicates the pure, ultra-fine nature, small crystallite size and  
276 negating the possibility of mixed phases biominerals.

277 The EDX microanalysis of the bioprecipitated crystals as presented in Fig. 5. The elemental profiles of  
278 the examined samples exhibited typical characteristic elemental peaks at 0.277, 0.525 and  
279 3.69keV with atomic percentages range of (17-20 %), (42-51%), and (32-40%), which is related to  
280 the binding energies of carbon, oxygen and calcium, respectively. Additionally, there were other  
281 EDX peaks could be noticed in a small percentage such as Na and Cl, which proposed to be ingredients  
282 of culture media. This result is in agreement with **Han et al., (2018)**. Obviously, vaterite samples of  
283 anaerobic culture of strains VIP and EM4 displayed another additional phosphorus (P) peak (2.013  
284 keV) with considerable percentage assessed by 2-3%. Apparently, its presence could suggest  
285 being a biological origin, where, it represents essential constituent of bacterial biomolecules such as  
286 phospholipids, nucleic acids, proteins and/or polysaccharides. The involvement of vaterite with P is  
287 considered to be advantageous by providing stabilization and subsequently preventing transformation to  
288 calcite form. The same result was obtained with other research groups (**Ghosh et al., 2019**).  
289 Generally, the calcium peaks intensities and their corresponding atomic percentages, which were higher  
290 than carbon peak, may reflect higher purity in structure as implied by **Caicedo-Pineda et al., (2018)**.

291 The detailed characterization about the morphology, texture, surface and size of bio-deposited  $\text{CaCO}_3$   
292 crystals were studied by SEM. As shown in Figure 6A, approximately square or cubic shape  $\text{CaCO}_3$   
293 crystals in the range of 0.2 to 3.7  $\mu\text{m}$  was noticed with strain 71A under aerobic condition. Close up  
294 view of these crystals depicted smooth surface embedded with rod shaped bacterial cells Fig. 6 (B) and  
295 some wrinkled surface globules with internal small holes Fig. 6 (B), indicated by arrows). Higher  
296 magnification in another sector displayed casts of bacterial cells and rhombohedral particles cemented  
297 in mucous matrix as referred by head arrow Fig. (6C), such mucilaginous like material could be  
298 considered as a polysaccharide excreted by carbonatogenic bacteria. This result concurred with the  
299 previous report in which rhombohedral calcite was produced by *B. megaterium* and embedded in slimy  
300 matrix (**Kaur et al., 2013**). On the other hand, the calcite formed anaerobically appeared as aggregated

301 grains in size of 6.2 to 22.4  $\mu\text{m}$  and irregular shaped clusters Fig. 6 (D). Additionally, subhedral  
302 rhombohedral particles with defined faces and edges were observed accompanying with anhedral  
303 crystals Fig. 6 (E). The presence of mucoid substance that encompassed these particles were also  
304 detected Fig. 6 (E), head arrows. Further, round shaped calcified bacterial cells were evident on the  
305 surface of bioliths Fig. 6 (F). Such change in cell morphology at anaerobic conditions could be ascribed  
306 to unfavorable conditions that lead to sporulation of vegetative cells. Virtually, the sporulation  
307 capability of strain 71A seemed to be advantageous; particularly in prospective applications with harsh  
308 conditions as self-healing of concrete cracks. In fact, bacterial spores are able to withstand adverse  
309 environmental conditions to maintain cell viability (**Vashisht et al., 2018**). However, the calcite  
310 mineralized by aerobic culture of strain VIP exhibited coarse, imbricated subhedral, rhombohedral  
311 minerals with size ranged from 0.79  $\mu\text{m}$  to 1.63  $\mu\text{m}$  Fig 6 (G). Viewed at higher magnification Fig 6  
312 (H), the calcite crystals were accumulated compactly and assembled into stacks like structures. The  
313 bacterial cell contours were evident on calcite surface (indicated by arrows) Fig. 6 (I). Interestingly,  
314 calcite crystals with size range (1–10  $\mu\text{m}$ ) were produced during nitrate assimilation process by  
315 saprophytic fungus *Alternaria sp.* (**Hou et al., 2011**), which is consistent with results of the present  
316 study.

317 Remarkably, the vaterite of anaerobic strain VIP culture showed series of globules, spherulite crystals  
318 with size range of 12.3 to 61.8  $\mu\text{m}$  Fig. 6 (J & K). In addition, the bacterial imprints were indicated by  
319 cavities on smooth surface of the sphere Fig. 6 (L). Such imprints emphasized the intrinsic role of  
320 bacterial cell as nucleation site for  $\text{CaCO}_3$  precipitation, which totally concurred with the finding of **Li**  
321 **et al., (2012)**. In coincident with our results, **Rodriguez-Navarro et al., (2012)** demonstrated the ability  
322 of *Myxococcus sp.* to induce different morphologies of both vaterite and calcite depending on growth  
323 conditions and medium composition. On the other hand, the spiny vaterite beads (5.5 – 77.6  $\mu\text{m}$ ), which  
324 spiked with triangular sharp point surface, were formed by strain EM4 Fig. 6 (M). The magnified field  
325 of vaterite pellets illustrated ramified  $\text{CaCO}_3$  crystals encapsulated the hyphae of *Streptomyces* cells  
326 Fig. 6 (N & O). Similar results were obtained with **Caicedo- Pineda et al., (2018)**. Otherwise,

327 elongated plate-like crystals were produced by the actinomycete culture of *Thermomonospora* sp.

328 **(Rautaray et al., 2004).**

329 Notably, the bacterial cells and their corresponding metabolic activity were prerequisite for the  
330 bioprecipitation of CaCO<sub>3</sub> crystals, particularly with absence of such deposition in abiotic negative  
331 control **(Han et al., 2017)**. Generally, the nitrate bioreduction is the predominant mechanism in CaCO<sub>3</sub>  
332 precipitations, which was summarized in the equation (1) to be followed by the strains under study  
333 **(Ivanov et al., 2015):**

335 In fact, the studied bacterial species reduced nitrate by NR enzymes to oxidize the organic carbon and  
336 electron donor (acetate) for energy generation and cells proliferation. As referred by **Singh et al.,**  
337 **(2015)** and **Zhu and Dittrich, (2016)**, protons were consumed continuously during such process and  
338 resulted in production of respired CO<sub>2</sub> and bicarbonate which ultimately elevated pH and alkalinity of  
339 ambient medium **(Hou et al., 2011; Zhu and Dittrich, 2016)**. Under this circumstance, the  
340 precipitation/crystallization process is initiated in two main steps based on the crystal growth theory  
341 **(Trushina et al., 2014)**. The first is crystal nucleation, which a new solid phase in nanometer size forms  
342 in supersaturated solution **(Wu et al., 2017)**. The second step is crystal growth, which could be  
343 described as atom-by-atom addition to the newly formed nuclei. Consequently, the growth of larger  
344 crystals and increasing in the particles size either occur randomly or oriented at the expense of smaller  
345 crystals or nanoaggregates **(Zhou et al., 2010)**. The particles with lower surface charge tend to  
346 coagulate and agglomerate to each other in a crystallographically oriented manner till reach to the most  
347 stable crystals with particular size that cause sedimentation. Thus, at this point the precipitation process  
348 is completed **(Rodriguez-Navarro et al. 2007; Trushina et al., 2014)**. Substantially, such precipitation  
349 process is not genetically or biologically controlled by the microorganism itself, but mediated by the  
350 physico-chemical properties of the surrounding environment **(Caicedo-Pineda et al., 2018)**.

351 Noteworthy in this context is nucleation of crystals and solution supersaturation, which determine the  
352 size and polymorphic form of precipitated crystals (**Vekilov, 2010**). Where, crystal nucleation  
353 dominates over crystal growth at a relatively higher degree of supersaturation, which ultimately  
354 generates smaller size with approximately identical shaped crystals. On the other hand, at low  
355 supersaturation, the nucleation is slow and crystals grow faster than they do nucleate, resulting in  
356 aggregates of large crystals of various sizes forms (**Rodriguez-Navarro et al. 2007; Wu et al., 2017**).  
357 Such principle could explain the formation of small size deposits at aerobic cultures. In addition, it was  
358 suggested that anaerobic cultures of strains 71A and VIP excreted certain polysaccharides with adhesive  
359 nature that stickled tightly the fine particles into larger crystals. In agreement with these results,  
360 **Shirakawa et al., (2011)** stated that under static conditions, culture of *L. sphaericus* precipitated larger  
361 CaCO<sub>3</sub> crystals than in shaken cultures.

362 In the same extent, as pointed out by **Rodriguez-Blanco et al., (2017)**, the structure, morphology,  
363 stability and crystallization pathway of CaCO<sub>3</sub> precursor to either vaterite or calcite governorates by  
364 several factors. These include binding strength of Ca<sup>2+</sup> and CO<sub>3</sub><sup>2-</sup> ions within the CaCO<sub>3</sub> precursor  
365 aggregates, solubility, and the dissolution rate of CaCO<sub>3</sub> precursor, which all are pH-dependent. It is  
366 substantial to mention that alternation in pH values contributes in the ionic strength, which consequently  
367 effects on solution saturation. Where, higher supersaturation occurs at higher pH, alkalinity and  
368 carbonate ions concentrations. In addition, at higher supersaturation, the crystals with higher solubility  
369 and lower stability form first and vice versa as described by the Ostwald's law of stages (**Rodriguez-  
370 Navarro et al. 2007; Trushina et al., 2014**). That could explain vaterite formation by anaerobic culture  
371 of strain VIP and strain EM4; where higher metabolic activity accompanying with nitrate dissimilation  
372 process led to increase carbonate content and rapidly elevating pH values 9.58 (VIP) and 9.7 (EM4) to  
373 the point of supersaturation with respect to vaterite. On the other hand, under relatively low  
374 supersaturation, calcite formed by aerobic culture of strain VIP, aerobic and anaerobic cultures of strain  
375 71A at pH 8.9, 8.5, and 8.78, respectively. As pointed out by **Rodriguez-Navarro et al., (2012)**, the  
376 formation of vaterite and calcite were promoted at alkaline (8.5-10.5) and neutral pH (7), respectively.  
377 On contrary, **Rautaray et al., (2004)** stated that synthesis of vaterite by *Verticillium sp.* was facilitated

378 at low pH conditions (5.3), whereas calcite is favorably formed at pH more than 10 (**Ramakrishna et**  
379 **al., 2016**).

380 Besides pH, there are several key factors governed the type, crystal size and polymorph of the  
381 biodeposited crystals including; bacterial type, nucleation sites abundance, calcium concentrations,  
382 calcium precursor type, media composition and incubation conditions (**Anbu, et al., 2016; Chaparro-**  
383 **Acuña et al., 2018**). Accordingly, the bacterial species was considered being the MICCP determinant in  
384 the current study. Therefore, it is plausible to mention that bacterial surfaces properties could also  
385 influence greatly on phase and morphology of CaCO<sub>3</sub> through heterogeneous nucleation. It is promoted  
386 by coupling and binding of negatively charged functional (macro) molecules in the bacterial cell wall  
387 and positively charged cations (e.g. Ca<sup>2+</sup>). In general, the bacterial cell wall consists of peptidoglycans,  
388 teichoic lipoteichoic acids, lipids and lipopolysaccharide, which provide the negative charge of cell  
389 wall. As reported by **Anbu, et al., (2016)**, Ca<sup>2+</sup> ions prevented from accumulation inside the cell and  
390 adsorbed more frequently on cell envelope due to potency of the cell for ionic selectivity. Thereby, Ca  
391 <sup>2+</sup> ions were actively transferred out through passive diffusion by the action of an ATP-dependent  
392 pump which is located close to outside of the cell. With continuous H<sup>+</sup> uptake, higher Ca<sup>2+</sup>  
393 concentration and higher pH are emerged surrounding the cell, creating nanoscale neighborhood that  
394 facilitate precipitation and crystal growth of CaCO<sub>3</sub> as described in equations 2, 3 and 4 (Li et al., 2011;  
395 Singh, 2019):

399 Remarkably, heterogeneous nucleation is commonly occurred process in nature (**González-Muñoz et**  
400 **al., 2014**). Furthermore, other bacterial components such as lipids, glycoproteins, proteins,  
401 proteoglycans and extracellular polymeric substances (EPS) could provide additional nucleation site for  
402 CaCO<sub>3</sub> precipitation during carbonatogenesis process (**Li et al., 2011; Ghosh et al., 2019**). Such

403 organic macromolecules are acidic polyanionic polymers which include carboxylic (R-COO<sup>-</sup>),  
404 phosphatic (R-PO<sub>4</sub><sup>2-</sup>) or sulfonate (R-SO<sub>3</sub><sup>-</sup>) functional groups, and can serve as promoters or inhibitors  
405 for crystals biomineralization (**Szcześ et al., 2018**).

406 Actually, when charged functional groups of EPS exist in a random distribution, they couple to metals  
407 in a disordered arrangement, which obstruct crystal nucleation. However, the presence of EPS  
408 functional groups in periodic and ordered array lead to stereo chemical gathering between the organic  
409 matrix and the newly-formed crystals and hence promotes heterogeneous nucleation (**González-Muñoz**  
410 **et al., 2014**).

411 Virtually, the culture of strain VIP might exhibit different metabolic products, proteins or EPS under  
412 different aeration conditions, which thereafter affected on the kinetics of crystallization process. Where,  
413 the biomolecules under certain condition may exhibit great affinity to certain face of specific polymorph  
414 and will adsorb onto these faces, causing alterations in crystals nucleation or growth stages of the  
415 affected polymorph on the account of the others (**Trushina et al., 2014**). Notably, EDX analysis Fig. 4  
416 (D & E) elucidated the incorporation of phosphorus peak with precipitated vaterite of both EM4 and  
417 anaerobic culture of VIP strains. That could explain the stability of such metastable phase and inhibition  
418 of its conversion to stable phase (aragonite or calcite). Such biologically originated phosphorus exhibits  
419 certain affinity to Ca<sup>2+</sup>. As it preferentially complexes with crystal nucleus and adsorbs on specific site  
420 during crystal growth causing growth inhibition; generating metastable vaterite (**Trushina et al., 2014**).  
421 It is noteworthy to mention that *Streptomyces* cell wall contain teichoic, which contains 1, 5-poly  
422 (ribitol phosphate) chain along with poly (glycerol phosphate) unites linked together by phosphodiester  
423 bonds (**Streshinskaya et al., 2003**). Besides, it also contains diamino acid, LL-diaminopimelic acid  
424 accompanied by glycine (**Nakamura et al., 1977**), which eventually confirm vaterite stabilization.  
425 Several literatures documented that the preservation of bio-vaterite was favored by organophosphorous  
426 biomolecules or phosphorus-enriched medium (**Caicedo-Pineda et al., 2018**).

427 Interestingly, **Tourney and Ngwenya, (2009)** shed the light on the dissolved organic carbon, which  
428 liberated from EPS and bound with Ca<sup>2+</sup> ions, causing lowering of CaCO<sub>3</sub> saturation which

429 consequently enhances calcite precipitation over vaterite. Additionally, **Kawaguchi and Decho, (2002)**  
430 declared that the association of specific proteins with EPS of *Schizothrix sp.* favored aragonite and  
431 calcite polymorph selection. In the same sense, extracellular proteins excreted by the *Verticillium sp.*  
432 and *Thermomonospora sp.* influenced significantly on both crystal morphology and polymorph  
433 selectivity as refereed by **Rautaray et al., (2004)**.

434 However, it was recorded that the appropriate nutrient types (e.g. carbon/ energy source and nitrogen  
435 source) and their concentrations stimulate the bacterial growth rate and enzymatic system, and thus  
436 provide the required chemical species and appropriate conditions for precipitation (**Kaur et al., 2013**).  
437 Alternatively, the different calcium sources induce different mineral shape and polymorph (**Anbu, et**  
438 **al., 2016; Kim et al., 2016; Chaparro-Acuña et al., 2018**). Where, rhombohedral calcite and disk-  
439 shaped vaterite were induced by calcium chloride and calcium acetate, respectively. While, spherical  
440 shape vaterite was induced by calcium lactate and calcium gluconate (**Anbu, et al., 2016**).

441 Herein, despite acetate and calcium nitrate supported good growth and rapid metabolic activity for  
442 examined bacteria, but these factors had no effect on polymorphic selectivity of CaCO<sub>3</sub> minerals as it  
443 was fixed with all examined bacterial species. In correspondence with current study, **Rothenstein et al.,**  
444 **(2012)** reported that Ca-acetate in the culture media of *Halomonas halophila* displayed no effect on the  
445 mineralized polymorph. Apparently, the current study has obviously shown that the variation in size,  
446 morphology and mineral phase of the biodeposited mineral is driven by strain-specific differences.  
447 Generally, the calcite/vaterite selectivity is a complex process and controversial issue (**Rodriguez-**  
448 **Navarro et al. 2007; González-Muñoz et al., 2014**).

449 The studies on the formation of spherical vaterite crystals in synthetic systems are relatively scarce  
450 (**Rautaray et al., 2004, Rodriguez-Blanco et al., 2017**). Actually, different problems encountered  
451 during synthesis, crystallization and stabilization. In particular with its instability and rapidly  
452 transformation into more stable phases (calcite or aragonite) at room temperature, and in an aqueous  
453 solution. Besides, the reproducibility and shape/size control of vaterite are taken in consideration. To  
454 overcome the above-mentioned concerns, certain additives either organic or inorganic were applied.

455 Nitric acid and ammonia are among inorganic additives, which deemed as facilitating factors influence  
456 on the kinetics of vaterite production (**Trushina et al., 2014**). However, polymers such as, polyacrylic  
457 acid, poly (vinyl alcohol), polycarboxylic acid, polyvinylpyrrolidone and commercial copolymers;  
458 including poly (4-styrenesulfonate-co-maleic acid) (PSS-co-MA), calixarene dendrimers were the most  
459 frequently used. Moreover, different types of alcohols and some ionic surfactant were utilized as an  
460 effective stabilizing and polymorph controlling agents (**Trushina et al., 2014**). The traces of such  
461 compounds associated with vaterite particles could exhibit undesired impact especially in applying  
462 vaterite in drug delivery and pharmaceutical formulations. Thus, all the sights directed to use  
463 biomimetically synthesized substances such as gelatin (**Wu et al., 2017**), Chitosan (**Wu et al., 2011**),  
464 amino acids and proteins (**Trushina et al., 2014**).

465 Nonetheless, the natural and biological matter is even better as documented by **Wu et al., (2017)**.  
466 Where, the carbonatogenic bacteria of the current study serve as a source of carbonate ions makes this a  
467 truly biogenic approach for minerals synthesis; hence does not consider merely biomimetic process.  
468 Actually, the carbon dioxide utilized in biomineralization generated from metabolism of carbonatogenic  
469 bacteria themselves and was not provided by external source as reported in other biomimetic studies  
470 (**Rautaray et al., 2003; Han et al., 2018**). In the same manner, **Hou and co-workers, (2011)** found  
471 that the nitrate uptake by *Alternaria* sp. caused of CaCO<sub>3</sub> formation via sequestration of respiratory CO<sub>2</sub>  
472 and thus reduce its emission and indirectly diminishing the rate of global warming.

473 Finally, the total biological synthesis of calcite and vaterite crystals under nitrate dissimilation  
474 conditions by strains 71A, VIP, and EM4 has not been reported previously. These carbonatogenic  
475 bacteria with their implications in crystal engineering open up the possibility to various prospective  
476 applications include; bioremediation of building stone, monuments/statuary,  
477 consolidation/strengthening of soil/sand, the reduction of the porosity and permeability of geological  
478 formations. Besides, the characteristic features of vaterite [the biocompatibility, biosafety,  
479 biodegradability, high (solubility, porosity, specific surface area), dispersion, accessibility and pH-  
480 sensitivity properties of CaCO<sub>3</sub>] make it highly appealing in biomedicine applications such as

481 bone/teeth implants, sensor applications and drug delivery (Rautaray et al., 2004; Poelvoorde, 2017).  
482 Additionally, the overall carbonatogenic process would be utilized in softening of hard water and CO<sub>2</sub>  
483 capturing from atmosphere and wastewater treatment systems in prospective studies.

#### 484 4. Conclusion

485 In conclusion, for the first time the present study demonstrated that the bacterial strains *L. sphaericus*  
486 (71A), *R. planticola* (VIP), and *S. pluricolaroscens* (EM4) isolated from Egyptian non-calcareous  
487 niches, induced carbonatogenesis process through nitrate reduction under aerobic and anaerobic  
488 conditions. XRD, EDX and SEM techniques were used to characterize precipitated CaCO<sub>3</sub>, which  
489 found to differ in their properties according to the type of strain as well as growth conditions.  
490 Precipitated CaCO<sub>3</sub> was either calcite or vaterite. Overall, carbonatogenesis process via nitrate  
491 reduction is totally biological, ecofriendly, inexpensive, and promotes CaCO<sub>3</sub> precipitations without  
492 accumulation of toxic by-product such as ammonia.

493 **Data availability.** The data of this study are available for public after a request to the corresponding  
494 author

495 **Author contributions.** The authors ME, SZ and DA contributed to plan of the work, results explanation  
496 manuscript writing and data analysis. AK helped in the practical part.

497 **Competing interests.** The authors declare that they have no conflict of interest.

659 **Figures legends**

660 **Figure 1:** Neighbour-joining phylogenetic tree based on 16S rDNA gene sequences, illustrating the  
661 relationships between carbonatogenic strains 71A, VIP and EM4 and related species retrieved from  
662 NCBI GenBank, their accession numbers are shown in parentheses. The bootstrap values above 50%,  
663 expressed as percentages of 1000 replications are indicated at the branch points.

664 **Figure 2:** The morphological differences of calcium carbonate crystals precipitated by carbonatogenic  
665 strains in liquid CCP media; A)-aerobic culture of strain 71A, B)-anaerobic culture of strain 71A, C)-  
666 aerobic culture of strain VIP, D)- anaerobic culture of strain VIP, E)- aerobic culture of strain EM4; F,  
667 G, H, I and K the air dried crystals with the same previous order.

668 **Figure 3:** Dynamic analysis of carbonatogenesis process associated with changes of pH,  $\text{NO}_3^-$   
669 concentration,  $\text{NO}_2^-$  concentration, cell growth, NR activity, EC and  $\text{CaCO}_3$  weight, mediated by A)-  
670 aerobic culture of strain 71A, B)- anaerobic culture of strain 71A, C)- aerobic culture of strain VIP, D)-  
671 anaerobic culture of strain VIP and E)-aerobic culture of strain EM4. The average of three replica were  
672 performed for each one. To adjust the scale, some parameters are multiplied and/or divided as indicated  
673 on the figures.

674 **Figure 4:** XRD profile of  $\text{CaCO}_3$  precipitated by A)- aerobic culture of 71A, B)-anaerobic culture of  
675 71A, C)- aerobic culture of VIP, D)- anaerobic culture of VIP and E)- EM4 culture.

676 **Figure 5:** EDX crystallographic pattern of  $\text{CaCO}_3$  precipitated by A)- aerobic culture of 71A, B)-  
677 anaerobic culture of 71A, C)- aerobic culture of VIP, D)- anaerobic culture of VIP and E)- EM4 culture.

678 **Figure 6:** SEM micrographs of  $\text{CaCO}_3$  crystal formed by nitrate reducing strains. A, B, C)- crystals  
679 from aerobic culture of 71A, D, E, F)- crystals from anaerobic culture of 71A, G, H, I)- crystals from  
680 aerobic culture of VIP, J, K, L)- crystals from anaerobic culture of VIP and M, N, O)- crystals from  
681 EM4 culture.
