Abstract. Net community production (NCP) in the surface water of the northern Gulf of Mexico (nGOM) and its coupling with the CO₂ system were examined during the productive spring season. NCP was estimated using multiple approaches: 1) underway O₂ and Ar ratio, 2) oxygen changes during light/dark bottle oxygen incubations, and 3) non-conservative changes in dissolved inorganic carbon or nutrients. These methods all showed high spatial variability of NCP and displayed similar pattern along the river-ocean mixing gradient showing high production rates in the plume region. NCP⁰²Ar estimated from high-resolution O₂ and Ar underway measurement indicated heterotrophic condition at the high-nutrient and high-turbidity Mississippi river end (-51.3±11.9 mmol C m⁻² d⁻¹ when salinity < 2) resulting from the influence of terrestrial carbon input and light limitation on photosynthesis. High NCP⁰²Ar rates (150.0±59.2 mmol C m⁻² d⁻¹, up to 235.4 mmol C m⁻² d⁻¹) were observed in the Mississippi and Atchafalaya plume at intermediate salinities between 15 to 30 where light and nutrient were both favourable for phytoplankton production. NCP⁰²Ar rates observed in the high-salinity, oligotrophic offshore waters (salinity > 35.5) were close to zero due to nutrient limitation. Air-sea CO₂ fluxes generally showed corresponding changes from being a strong CO₂ source in the river channel (55.5±7.6 mmol C m⁻² d⁻¹), to a CO₂ sink in the plume (-13.4±5.5 mmol C m⁻² d⁻¹), and to be nearly in equilibrium with the atmosphere in offshore waters. Overall, the surface water of the nGOM was autotrophic during spring in 2017 with an area-weighted mean NCP⁰²Ar of 21.2 mmol C m⁻² d⁻¹ and as a CO₂ sink of -6.7 mmol C m⁻² d⁻¹. A temporal mismatch between in situ biological production and gas exchange of O₂ and CO₂ was shown through a 1-D model to result in decoupling between NCP⁰²Ar and CO₂ flux (e.g., autotrophic water as a CO₂ source outside the Mississippi River mouth and heterotopic water as a CO₂ sink in the Atchafalaya coastal water). This decoupling was a result of in situ biological production superimposed on the lingering background pCO₂ from the source water because of the slow air-sea CO₂ exchange rate and the buffering effect of the carbonate system.
1 Introduction

The continental shelf is among the most biologically active areas of the biosphere and plays a significant role in global biogeochemical cycles (Chen and Borges, 2009; Chen and Swaney, 2012; Gattuso et al., 1998; Muller-Karger et al., 2005). Despite its moderate surface area (~7%), the continental shelf accounts for 14-30% of net ecosystem production (Gattuso et al., 1998), 80% of organic matter burial (Gattuso et al., 1998), and 15-21% of the CO₂ uptake of the global ocean (Cai, 2011; Cai et al., 2006; Chen and Borges, 2009; Laruelle et al., 2010). Moreover, anthropogenic impacts have substantially changed the nutrient and carbon loads delivered to the coastal oceans (Bauer et al., 2013; Regnier et al., 2013; Yang et al., 2018), with associated development of a series of environmental problems, e.g., coastal eutrophication, hypoxia, and acidification (Cai et al., 2011; Diaz and Rosenberg, 2008; Rabalais et al., 2014; Wallace et al., 2014). Understanding and quantifying how these impacts affect the metabolic balance and CO₂ fluxes of coastal systems is of critical interest to scientists and policy-makers. However, the substantial heterogeneity resulting from physical and biogeochemical interactions makes assessing metabolic state and carbon flux a challenging task in dynamic coastal environments.

Net community production (NCP) is defined as the difference between gross primary production and community respiration (Eppley and Peterson, 1979; Sarmiento and Gruber, 2006) and indicates whether the ecosystem is a net source or sink of organic matter (Eppley and Peterson, 1979; Sarmiento and Gruber, 2006). NCP in the mixed layer plays an important role in regulating the surface CO₂ and O₂ dynamics. It also represents the amount of organic carbon available for export to the subsurface, which is closely related to bottom water biogeochemical processes, e.g., the development and maintenance of hypoxia.

The northern Gulf of Mexico (nGOM) is a river-dominated continental shelf (McKee et al., 2004) with NCP and CO₂ dynamics significantly affected by the terrestrial inputs of carbon and nutrients from the Mississippi-Atchafalaya River system (Lohrenz et al., 2014). The CO₂ variability in the nGOM has been extensively investigated by high-resolution underway measurement of the partial pressure of CO₂ (pCO₂) (Huang et al., 2015). High terrestrial inorganic and organic carbon loading results in CO₂ oversaturation and net CO₂ efflux to the atmosphere in the river channel and estuary of the Mississippi River (Cai, 2003; Guo et al., 2012; Huang et al., 2015; Lohrenz et al., 2010). On the continental shelf, reduced pCO₂ observed in the Mississippi plume (sink for atmospheric CO₂) was attributed to strong primary production supported...
by the excessive riverine nutrient loads (Guo et al., 2012; Huang et al., 2015; Lohrenz et al., 1990; 1999; 2014). With the enhanced surface production and subsequently subsurface respiration of the sinking organic matter, recurring bottom hypoxia that covers large portions of the Louisiana-Texas shelf has been observed in summer when stratification limits O\textsubscript{2} replenishment (Bianchi et al., 2010; Obenour et al., 2013; Rabalais et al., 2002). Springtime riverine nutrient flux and subsequent biological production in surface water play a critical role in determining the size of the summertime bottom-water hypoxia area in the nGOM (Justić et al., 1993; Turner et al., 2012). The rapid subsurface respiration also leads to a significant decrease in pH and a weakening of acid-base buffer capacity, which leads to the enhanced coastal ocean acidification problem (Cai et al., 2011).

Previous NCP studies in the nGOM have been mainly based on the oxygen changes during light/dark bottle oxygen incubations and non-conservative removal of dissolved inorganic carbon or nutrients (Cai, 2003; Huang et al., 2012; Guo et al., 2012; Murrell et al., 2009; 2013). However, the detailed relationship between NCP and CO\textsubscript{2} dynamics remains unclear because of the low spatial resolution of the conventional NCP measurements based on discrete samples. In this study, we present the first attempt to obtain high-resolution NCP\textsubscript{O2Ar} estimates from continuous underway measurement of oxygen to argon ratio (O\textsubscript{2}/Ar) in the nGOM in spring 2017. The NCP\textsubscript{O2Ar} result was compared to those derived from traditional approaches to evaluate the consistency of NCP estimates from various methods. Meanwhile, these NCP methods are associated with different temporal and spatial scales and are differently affected by biological and physical processes. By making NCP estimates using the different methods we can get a more robust understanding of the overall metabolism of the system. The simultaneous underway determination of NCP\textsubscript{O2Ar} and pCO\textsubscript{2}, together with measurements of dissolved oxygen (DO), dissolved inorganic carbon (DIC), total alkalinity (TA), nutrients, and other environmental parameters, allow us to better constrain the variability and controls of the metabolic balance and CO\textsubscript{2} flux in the nGOM. We also use a 1-D model to investigate the relationship between NCP and air-sea fluxes of O\textsubscript{2} and CO\textsubscript{2}. 
2 Methods

2.1 Sample collection and measurements

The cruise was conducted onboard RV Pelican during 6-16 April 2017. The study region covered the Mississippi and Atchafalaya estuaries and the adjacent Louisiana continental shelf (Fig. 1). Vertical water column profiles of temperature, salinity, DO, chlorophyll fluorescence (Chl-a), and photosynthetically active radiation (PAR) were measured by a SeaBird CTD system (SBE 911plus) at 83 sampling stations (Fig. 1). Discrete water samples for DIC, TA, DO, and nutrients were collected from 3-12 depths depending on the bottom depth and vertical profiles of temperature, salinity and DO. River water samples of the Mississippi (89.98° W, 29.85° N) and Atchafalaya (91.21° W, 29.70° N, Fig. 1) were taken on 5 April, one day prior to the cruise, to identify the DIC and TA concentrations of the river end members. Samples for DIC and TA were collected in 250 mL borosilicate glass bottles and preserved with 50 µl of saturated HgCl₂ solution (Dickson et al., 2007). DIC was measured by non-dispersive infrared measurement on the CO₂ stripped from the acidified sample (AS-C3, Apollo SciTech). TA titrations were conducted with a ROSS™ combination electrode 8102 (Thermo Fisher Scientific) on a semi-automated titrator (AS-ALK2, Apollo SciTech). The precision of DIC and TA measurements were both 2 µmol kg⁻¹. DIC and TA measurements were calibrated, both with accuracy better than 0.1 %, with certified reference materials provided by A. G. Dickson, Scripps Institution of Oceanography. DO in discrete samples was measured by a Shimadzu UV-1700 at 25 °C using the spectrophotometric method following Pai et al., (1993) with an accuracy of 0.2 %. For nutrient analysis, water from each Niskin bottle was immediately filtered through 0.22 µm, sterile, polyethersulfone syringe filters and stored frozen for subsequent nutrient characterization. Samples were analyzed in duplicate for dissolved NO₃ (NO₃⁻ + NO₂⁻) by Cu-Cd reduction followed by azo dye colorimetry using a Lachat Instruments QuikChem® FIA+ 8000 Series Automated Ion Analyzer at the Louisiana Universities Marine Consortium as described previously (Roberts and Doty, 2015). Standard curves were prepared using standard NO₃-N and NO₂-N stock solutions (Hach, Loveland CO) and yielded r² values of ≥ 0.999.

2.2 Underway measurements

The underway system was fed by the ship’s seawater supply from an inlet located at an approximate depth of 2.5 m. The flow-through system and the Multiple Instrument Data Acquisition System (MIDAS) provided measurements on sea surface
temperature, conductivity (Seabird SBE 21 Thermosalinograph), Chl-a (Turner Model 10 Series Fluorometers), and light transmittance (WETLabs 25-centimeter path length transmissometer). MIDAS also integrated data from the ship’s meteorological suite: wind, barometric pressure, temperature, and relative humidity (R.M. Young) and PAR (LI-COR LI-190SZ).

Underway seawater $pCO_2$ was measured with a precision of 0.1 $\mu$atm by an automated flow-through $pCO_2$ measuring system (AS-P2, Apollo SciTech) with a shower head equilibrator and a non-dispersive infrared gas detector (LI-7000, LI-COR) (Huang et al., 2015). The $pCO_2$ measurement was calibrated twice daily against 3 certified gas standards (150.62, 404.72, and 992.54 ppm) and the accuracy was better than ±2 $\mu$atm. Underway $pCO_2$ system alternated measurements on a stream of seawater split from the same inlet for the MIDAS and a stream of outside air from the bow of the vessel away from chimney contamination. The atmospheric $pCO_2$ was measured every 3 hours automatically. The underway DO was measured by an Aanderaa 4835 optode which was calibrated against discrete surface water values by spectrophotometric measurements. Underway high-resolution measurements of $O_2$/Ar were made by equilibrator inlet mass spectrometry as described by Cassar et al., (2009). Briefly, a fraction of underway seawater (the same supplied to the $pCO_2$ measuring system) was pumped through a gas-permeable membrane contactor cartridge at a flow rate of 100 mL min$^{-1}$. The cartridge was connected to a quadrupole mass spectrometer (Pfeiffer Prisma) through a fused-silica capillary which continuously sampled headspace gases for $O_2$/Ar measurement. As the atmospheric $O_2$/Ar is essentially constant relative to that in the surface water, calibrations of the $O_2$/Ar ion current ratio were conducted by sampling the ambient air every 3 hours through a second capillary (Cassar et al., 2009). The instrument precision estimated from the repeated measurements of atmospheric $O_2$/Ar was 0.3 %.

2.3 Calculations

The mixed layer depth (MLD) was defined as the depth at which the density changed by 0.03 kg m$^{-3}$ relative to the surface value and was calculated according to the density profiles at sampling stations. Air-sea $CO_2$ flux was calculated as:

$$F_{CO_2} = k_{CO_2} K_0 \Delta pCO_2_{2(sea-air)} = k_{CO_2} K_0 (pCO_{2meas} - pCO_{2air})$$

(1)
where $k_{CO2}$ is the gas transfer velocity of CO$_2$ calculated using the daily mean wind speed from the three-dimensional Coupled Ocean/Atmosphere Mesoscale Prediction System (COAMPS) (Hodur, 1997) and the coefficients of Sweeney et al., (2007). The COAMPS daily wind speed agreed well (mean difference = 0.4 m s$^{-1}$, figure not shown) with buoy measurements in our study region (s42047, s8768094, FRWL1, MRSL1, LOPL1, GISL1, PSTL1, and PILL1, data from the National Data Buoy Center, http://www.ndbc.noaa.gov/maps/WestGulf.shtml). $K_0$ is the CO$_2$ solubility coefficient calculated from the measured sea surface temperature and salinity (Weiss, 1974). $\Delta p_{CO2\text{sea-air}}$ is the difference between the measured $pCO_2$ in the surface water ($pCO_2\text{meas}$) and in the atmosphere ($pCO_2\text{air}$). Comparing to the large variations in $pCO_2\text{meas}$ (110-1800 µatm), the variability of $pCO_2\text{air}$ was minor (405 ± 4 µatm) so the $pCO_2\text{air}$ was set at the cruise average value of 405 µatm for the flux calculation. The negative $F_{CO2}$ corresponds to a net CO$_2$ uptake by the ocean (ocean as a CO$_2$ sink for the atmosphere). Air-sea O$_2$ flux was calculated as:

$$F_{O2} = k_{O2} \Delta O_2\text{2(sea-air)} = k_{O2} ([O_2\text{meas}] - [O_2\text{sat}])$$ (2)

where $k_{O2}$ is the gas exchange velocity of O$_2$ which was calculated in a similar way with that of $k_{CO2}$, $\Delta O_2\text{2(sea-air)}$ is the difference between the seawater DO concentration from the calibrated underway optode measurement ($[O_2\text{meas}]$) and the saturated DO concentration ($[O_2\text{sat}]$) calculated from the measured sea surface temperature and salinity (Garcia and Gordon, 1992). The oxygen saturation percentage (DO%) is calculated as $DO\% = [O_2\text{meas}] / [O_2\text{sat}]$.

### 2.4 NCP estimates

In this study, NCP rates were estimated by three different approaches: underway O$_2$/Ar measurements (NCP$_{O2Ar}$), light/dark bottle DO incubations (NCP$_{DO\text{-incub}}$), and non-conservative changes in DIC (NCP$_{ADIC}$) or NO$_x$ (NCP$_{NOx}$).

**NCP from the O$_2$/Ar method:** DO concentration in the surface water is affected by physical (e.g., changes in temperature, salinity, and atmospheric pressure, bubble dissolution and injection) and biological processes (photosynthesis and respiration). Ar and O$_2$ have similar responses to physical processes as they have similar solubility and temperature dependency (Garcia and Gordon, 1992; Hamme and Emerson, 2004). On the other hand, Ar is biologically inert and can be used to infer abiotic influences on oxygen. Contemporaneous measurements of O$_2$ and Ar thus allow the biologically-
induced O₂ changes to be isolated (Craig and Hayward, 1987). By measuring the biologically mediated oxygen supersaturation \( \Delta(O_2/Ar) \) (Cassar et al., 2011; Craig and Hayward, 1987; Jonsson et al., 2013; Kaiser et al., 2005):

\[
\Delta(O_2/Ar) = \frac{[O_2]/[Ar]}{[O_2]_{sat}/[Ar]_{sat}} - 1 \quad (3)
\]

the surface NCP can be approximated by the net air-sea biological oxygen flux (bioflux, mmol O₂ m⁻² d⁻¹) under a physically isolated mixed layer assumption (Jonsson et al. 2013):

\[
NCP_{O2Ar} = \text{bioflux} = k_{O_2}[O_2]_{sat}\Delta(O_2/Ar) \quad (4)
\]

The modeling study by Teeter et al., (2018) suggested that the bioflux accurately represents the exponentially weighted NCP over the past several residence times of O₂. The residence times of O₂ (MLD/gas transfer velocity of O₂, ~2.3 days during our cruise) refers to the length of time required to exchange O₂ between the mixed layer and the atmosphere (Kaiser et al., 2005; Teeter et al., 2018). To account for the wind speed history prior to the arrival of the ship at each station, the weighting technique of Reuer et al., (2007) modified by Teeter et al., (2018) was applied to calculate the gas exchange velocity of O₂ in this study.

*NCP from the DO incubation:* NCP was estimated with light/dark bottle incubation method at 43 CTD stations (Fig. 1). Surface water samples (~1.5 m) were collected from Niskin bottles into triplicate clear and black 300-ml BOD bottles (Wheaton). The initial oxygen saturation percentage and temperature in each bottle was measured by inserting a luminescent/optical dissolved oxygen probe (Hach LDO101, Hach Hq40d meter) into the bottle. Care was taken to avoid introducing air bubbles during this step. After recording the initial oxygen saturation percentage value, the probe was removed and the small volume displaced by the probe (~3 ml) was replaced with filtered seawater from an offshore, low nutrient site. The addition of DO to the bottle from the replacement water was considered small, on the order of the method detection limit of approximately 2 mmol m⁻³ d⁻¹ (Murrell et al. 2009; 2013). Clear and dark bottles were placed into a deck incubator screened at 50 % of ambient sunlight for 24 hours. The deck incubator was plumbed with flowing seawater from the MIDAS in order to maintain surface water temperatures. After 24 hours, the oxygen saturation percentage and temperature were measured again with the oxygen probe. DO concentrations obtained from the LDO probe were verified by a comparison with DO concentrations measured by the spectrophotometric method of Pai et al., (1993) in a subset of
samples (n = 14). The mean difference between the two methods of ±5 % was consistent with previous comparisons of probe measured versus Winkler measured DO based on several hundred comparisons (Murrell et al. 2013).

The respiration rate was calculated from the DO changes in the dark bottles \( R_{\text{dark}} \), mmol O\(_2\) m\(^{-3}\) d\(^{-1}\). The respiration rate was assumed to be uniform in the mixed layer, thus, the integrated respiration over the MLD \( \text{Resp}_{\text{int}} \), mmol O\(_2\) m\(^{-2}\) d\(^{-1}\) was calculated as \( \text{Resp}_{\text{int}} = R_{\text{dark}} \times \text{MLD} \). The gross primary production (GPP) varied with depth due to the reduction in light availability with increasing depth. The mean percentage of PAR (\%PAR) in the water column in relation to surface PAR \( E_0 \) was calculated at each station as:

\[
\text{%PAR} = \frac{E_0}{K_d \times \text{MLD}}(1 - e^{-K_d \times \text{MLD}}) \quad (5)
\]

where \( E_0 \) is 100 \%, light attenuation \( (K_d, \text{ m}^{-1}) \) is the rate of exponential decline in PAR as a function of depth as measured by the CTD. In our study, we assumed that GPP was linearly dependent on light up to a maximum GPP\(_{\text{max}}\) occurred when \%PAR = 50 \%. This assumption is based on previous measurements from this shelf that indicate photosynthesis begins to saturate at light level of ~200 \( \mu \text{mol quanta m}^{-2} \text{s}^{-1} \) (Lohrenz et al., 1994), which is roughly 50 \% of light in the surface mixed layer (Lohrenz et al., 1999). GPP\(_{\text{max}}\) was thus estimated as \( \text{GPP}_{\text{max}} = R_{\text{light}} - R_{\text{dark}} \), where \( R_{\text{light}} \) is the DO change rate in the light bottles. To calculate the integrated GPP in the mixed layer \( \text{GPP}_{\text{int}}, \text{ mmol O}_2 \text{ m}^{-2} \text{ d}^{-1} \), the GPP was scaled by the light environment in the MLD:

if \%PAR ≥ 50 \%, \( \text{GPP}_{\text{int}} = \text{GPP} \times \text{MLD} \quad (6) \)

if \%PAR < 50 \%, \( \text{GPP}_{\text{int}} = 2 \times \%\text{PAR} \times \text{GPP} \times \text{MLD} \quad (7) \)

The coefficient 2 in Eq. 7 was used so that the product of \( 2 \times \%\text{PAR} \) would scale from 0 to 1, i.e., GPP approaches GPP\(_{\text{max}}\) at \%PAR = 50 \%. Finally, the NCP integrated over the MLD \( \text{NCP}_{\text{DO-incub}}, \text{ mmol O}_2 \text{ m}^{-2} \text{ d}^{-1} \) was estimated as:

\[
\text{NCP}_{\text{DO-incub}} = (\text{GPP}_{\text{int}} - \text{Resp}_{\text{int}}) \quad (8)
\]

The standard errors of NCP\(_{\text{DO-incub}}\) from triplicate bottle incubations across all sites were on average about 16 \% of the mean.

**NCP from the non-conservative changes in DIC or nutrients:** NCP can also be estimated from the biological-induced deviations of DIC or nutrients from the conservative mixing. We applied a three end-member mixing model (Huang et al., 2012) to distinguish the contribution from conservative mixing \( (X_{\text{mix}}) \) and the biological-induced change \( (\Delta X_{\text{biol}}) \). The \( X_{\text{mix}} \)
was calculated from the fractions of gulf surface seawater \( f_{sw} \), the Mississippi River water \( f_{MR} \), and the Atchafalaya River water \( f_{AR} \) together with the corresponding end-member concentrations shown in Table 1:

\[
1 = f_{sw} + f_{MR} + f_{AR} \quad (9)
\]

\[
X_{\text{mix}} = X_{sw} * f_{sw} + X_{MR} * f_{MR} + X_{AR} * f_{AR} \quad (10)
\]

We used salinity and potential alkalinity \( \text{PTA} = \text{TA} + \text{NO}_3 \) (Brewer and Goldman, 1976) as the two conservative tracers to constrain \( f_{sw} \), \( f_{MR} \), and \( f_{AR} \) using a non-negative least square method (Lawson and Hanson, 1974). The concentrations of DIC\(_{\text{mix}}\) and NO\(_3\)\(_{\text{mix}}\) from conservative mixing can then be calculated from Eq. 10, and the biological-induced changes in DIC \( (\Delta\text{DIC}_{\text{NCP}}) \) and NO\(_3\) \( (\Delta\text{NO}_3\text{NCP}) \) were estimated as:

\[
\Delta\text{DIC}_{\text{NCP}} = \text{DIC}_{\text{meas}} - \text{DIC}_{\text{mix}} - \Delta\text{DIC}_{\text{gas}} \quad (11)
\]

\[
\Delta\text{NO}_3\text{NCP} = \text{NO}_3\text{meas} - \text{NO}_3\text{mix} \quad (12)
\]

where DIC\(_{\text{meas}}\) and NO\(_3\)\(_{\text{meas}}\) are the observed concentrations of DIC and NO\(_3\), and \( \Delta\text{DIC}_{\text{gas}} \) is the DIC changes induced by air-sea CO\(_2\) exchange. Note that \( \Delta\text{DIC}_{\text{NCP}} \) (mmol C m\(^{-3}\)) and \( \Delta\text{NO}_3\text{NCP} \) (mmol N m\(^{-3}\)) represent the cumulative NCP-induced changes in the concentrations of DIC and NO\(_3\) since the mixing of river water with oceanic water. In order to calculate the NCP rates derived from DIC \( (\text{NCP}_{\text{DIC}}, \text{mmol C m}^{-2} \text{ d}^{-1}) \) or NO\(_3\) \( (\text{NCP}_{\text{NO}_3}, \text{mmol N m}^{-2} \text{ d}^{-1}) \), the MLD and plume residence time \( (\tau) \) need to be considered (Cai, 2003):

\[
\text{NCP}_{\text{DIC}} = \Delta\text{DIC}_{\text{NCP}} * \text{MLD} / \tau \quad (13)
\]

\[
\text{NCP}_{\text{NO}_3} = \Delta\text{NO}_3\text{NCP} * \text{MLD} / \tau \quad (14)
\]

To facilitate comparison with previous studies (Guo et al., 2012, Huang et al., 2012, Cai, 2003), \( \tau \) values for the Mississippi plume were taken from Green et al., (2006) as 1, 1.5, and 6 days for salinity range of 0-18, 18-27, and 27-34.5 respectively. In our study, we only calculated NCP\(_{\text{DIC}}\) and NCP\(_{\text{NO}_3}\) for stations in the Mississippi plume because \( \tau \) for the Atchafalaya plume is not available.

**NCP unit conversion:** To facilitate the comparison of NCP estimates from the different approaches, NCP rates were converted to the same carbon units (mmol C m\(^{-2}\) d\(^{-1}\)) using the Redfield ratio of C:N:O\(_2\) = 106:16:138. The photosynthetic molar ratio of C:O\(_2\) for new and recycled production may vary between 1.1 (NH\(_4^+\) as nitrogen source) and 1.4 (NO\(_3^-\) as nitrogen source) (Laws, 1991). In our study region, the riverine input of NO\(_3^-\) was the main nitrogen source for biological
uptake (Table 1) and we considered the average Redfield ratio of C:O$_2 = 106:138$ to be appropriate. Although biological C:N uptake may differ from the Redfield stoichiometry (Geider and La Roche, 2002; Sambrotto et al., 1993), the applicability of the Redfield C:N ratio has been previously demonstrated in our study region (Huang et al., 2012; Xue et al., 2015) and confirmed in this study.

2.5 1-D model for NCP and gas exchange

A simple 1-D model was used to examine the relationship between NCP and air-sea fluxes of O$_2$ and CO$_2$. The environmental settings of the model were taken from the averaged condition during our study period: temperature = 22 °C, salinity = 35, TA = 2400 μmol L$^{-1}$, $p$CO$_{2air}$ = 405 μatm, MLD = 6 m, and wind speed = 6 m s$^{-1}$. The initial state of the seawater was set to be in equilibrium with the atmosphere, and the concentrations of DO and $p$CO$_2$ in the seawater were modulated by time-dependent NCP functions and air-sea gas exchange at hourly time steps. At each time step, the relative changes in concentrations of DIC, TA, and DO resulting from NCP were assumed to follow the ratio of 106:17:138 (Zeebe and Wolf-Gladrow, 2001). The $p$CO$_2$ was calculated from DIC and TA using the CO2SYS program (Pierrot and Wallace, 2006). The air-sea flux of O$_2$ and CO$_2$ were calculated following Eq. 1 and Eq. 2.

3 Results

3.1 General hydrological and biogeochemical characteristics

The Mississippi and Atchafalaya Rivers typically experience peak discharge and NO$_x$ loading in spring (Fig. S1). These peaks in spring 2017 occurred later than the average condition during 1997-2017 and the monthly mean values of discharge and NO$_x$ loading in April 2017 were slightly lower than the long-term mean values (Fig. S1). Surface water parameters (temperature, salinity, light transmittance, Chl-a, DO%, $p$CO$_2$, and $\Delta$O$_2$/Ar) showed high spatial variability on the inner and middle shelf (bottom depth < 50 m), with much lower variability observed on the outer shelf (bottom depth > 50 m) (Fig. 2). The highest physical and biogeochemical variations were observed in the Mississippi plume during 8-11 April and in the Atchafalaya coastal region during 15-17 April (Fig. 3). In spring when river discharge is high and the wind is typically downwelling-favourable, the Mississippi River freshwater generally flows westward in a contained nearshore current (Zhang et al., 2012; Lehrter et al., 2013). Our three end-member mixing model accurately reproduced the westward extension of the
Mississippi freshwater on the Louisiana shelf from the Mississippi bird’s foot delta (Fig. 2b and Fig. 4a). The model also suggested a westward Atchafalaya plume trajectory in a narrow band along the coast with little Atchafalaya freshwater was transported upcoast toward the Mississippi Delta (Fig. 4b). The pattern of the Mississippi and Atchafalaya freshwater transport agreed well with the multiple-year average condition (2005-2010) in April by hydrodynamic numerical simulation (Zhang et al., 2012). To better investigate the variability of surface water parameters, we divided the coastal region into four sub-regions: 1) the lower Mississippi River channel (Fig. S2, salinity < 2); 2) the Mississippi plume (Fig. 4a, east of 90.75° W, north of 28.30° N); 3) the high-turbidity Atchafalaya coastal water (Fig. 4a and Fig. 2d, 90.75-92.35° W, light transmittance < 20 %, named as HTACW hereafter); and 4) the Atchafalaya plume (Fig. 4b, 92.35-93.50° W, north of 29.00° N). Typical vertical CTD profiles are shown in the supplement (Figs. S2-S4) to demonstrate the different mixing conditions observed in the four sub-regions as well as other regions in the nGOM.

3.2 Estimates of NCP

In comparison to the discrete measurements of NCPDO-incub, NCPDIC, and NCPANOX, the underway O2/Ar measurements provided NCPO2Ar estimates with the highest resolution and most complete spatial coverage (Fig. 5). The NCPDO-incub, NCPDIC, and NCPANOX were mostly obtained at salinities higher than 20, while the NCPO2Ar covered the whole salinity range (0 to 36.4) providing more information on the NCP variability in the dynamic estuary environments. All methods suggested high variability of NCP in the surface water of the nGOM (Fig. 3c, Fig. 5) and these methods display similar spatial patterns with high production rates in the plume region around the Mississippi bird’s foot delta (Fig. 5). The results of NCPDIC (-19.0 to 274.9 mmol C m⁻² d⁻¹) and NCPANOX (1.6 to 314.0 mmol C m⁻² d⁻¹) were close to each other (Fig. 5c, d), and their ranges were similar to that of NCPO2Ar in the Mississippi plume (-99.6 to 235.4 mmol C m⁻² d⁻¹) (Fig. 3c). NCPDO-incub (-56.0 to 360.7 mmol C m⁻² d⁻¹) gave the highest NCP estimates in the Mississippi plume (stations C10, A7, and X3 in Fig. 5b and Fig. 3c). As NCPO2Ar is a backward exponentially weighted average rate (Teeter et al., 2018), it is less able to capture high NCP values due to the inherent averaging of the O2/Ar approach. Moreover, NCPO2Ar could be a poor estimate of daily production rate (e.g., NCPDO-incub in our study) when the mixed layer is not at steady state (Teeter et al., 2018). These could partly explain the observed difference between NCPO2Ar and NCPDO-incub in the dynamic Mississippi plume. In the high-salinity offshore waters, NCPO2Ar and NCPDO-incub both suggest low NCP rates close to zero (Fig. 5a, b). One major difference
between NCP_{O2Ar} and NCP_{DO-incub} is that the O₂/Ar method generated negative NCP estimates in the lower Mississippi River channel and in the HTACW while NCP_{DO-incub} suggested positive NCP rates in these regions (Fig. 5a, b).

### 3.3 Mississippi River channel and plume

Vertical CTD profiles showed strong surface stratification in the lower Mississippi River channel (Fig. S2). The light transmittance in the surface water of the river channel was close to zero (Fig. 6a) and the Chl-a concentrations were low (Fig. 6b) despite the ample nutrient availability (NO₃ up to 123.3 μmol/kg, Table 1). Similar to most inner estuaries (Borges and Abril, 2011; Chen et al., 2012; Chen and Swaney, 2012), high pCO₂ (up to 1803.0 μatm, Fig. 6c), undersaturated DO (83.7±0.8 %, Fig. 6d) and net CO₂ efflux (55.5±7.6 mmol C m⁻² d⁻¹, Fig. 6e) was observed in the lower Mississippi River channel. The negative NCP_{O2Ar} (-51.3±11.9 mmol C m⁻² d⁻¹, Fig. 6f) suggested net heterotrophic condition in the Mississippi River channel which contrasts with the positive NCP_{DO-incub} (94.5±11.6 mmol C m⁻² d⁻¹ Fig. 7c) measured by the DO incubation method.

The Mississippi plume and most offshore regions were characterized by surface stratification, which was mainly caused by the buoyancy of fresher surface water in the plume and vertical temperature gradient in the offshore region (Fig. S3). With the increasing light transmittance (Fig. 6a) in conjunction with persistence of riverine-derived nutrient concentrations (Fig. 7a) along the Mississippi plume flow path, phytoplankton biomass reached high levels at intermediate salinities of 15-30 (Fig. 6b). The high Chl-a concentrations in the plume region corresponded to large decreases in pCO₂ (down to 113.9 μatm, Fig. 6c) and strong oceanic CO₂ uptake (up to -42.7 mmol m⁻² d⁻¹, Fig. 6e), as well as elevated DO% (up to 180.1 %, Fig. 6d) and NCP rates (Fig. 6f). The observed high NCP rates (e.g., up to 235.4 mmol C m⁻² d⁻¹ in NCP_{O2Ar}, up to 360.7 mmol C m⁻² d⁻¹ in NCP_{DO-incub}, Fig. 7c) are within the range of prior estimates for this region during spring season (-238 to 624 mmol C m⁻² d⁻¹, Cai, 2003; Guo et al., 2012; Huang et al., 2012; Lohrenz et al., 1990; 1997; 1999), and are among the highest in large river estuarine and shelf waters (Cooley and Yager, 2006; Dagg et al., 2004; Ning et al., 1988; Ternon et al., 2000).

### 3.4 Atchafalaya plume and HTACW

The Atchafalaya River discharges in a shallow broad, low-gradient shelf (10 m isobath doesn’t occur until more than 40 km offshore of the delta, Fig. 1) which frequently experiences cross-shelf currents (Roberts and Doty, 2015). The Atchafalaya
plume water, extended westward in a narrow band along the coast (Fig. 4b), generally showed similar biogeochemical variability to that observed in the Mississippi plume (Fig. 6). Elevated Chl-a, DO%, and NCP$_{O2Ar}$ were also observed at intermediate salinities of 15-30 in the Atchafalaya plume together with a dropdown in $pCO_2$ and oceanic $CO_2$ uptake (Fig. 6). For both the Mississippi and Atchafalaya plume regions, the three end-member mixing model suggests that the enhanced biological production resulted in significant deviations of DIC and NO$_x$ from the conservative mixing lines (Fig. 8). The amplitudes of the non-conservative biological removal of nutrients (up to 35 $\mu$mol kg$^{-1}$ in $\Delta$NO$_{NCP}$, Fig. 8a) and DIC (up to 250 $\mu$mol kg$^{-1}$ in $\Delta$DIC$_{NCP}$, Fig. 8b) are similar to the findings of previous studies in the nGOM (Cai, 2003; Guo et al., 2012; Huang et al., 2012). The biological uptake ratio of $\Delta$NO$_{NCP}$ and $\Delta$DIC$_{NCP}$ (0.14 in Fig. 8c) was close to the Redfield N:C ratio (16:106). However, NCP$_{O2Ar}$ suggested that the southwest part of the Atchafalaya plume was heterotrophic (around 29.30° N, 93.50° W, Fig. 5a). A detailed examination of the CTD profiles revealed that the water column in this area was vertically well-mixed (Fig. S4), which was different than the stratification condition observed in other plume regions. The HTACW was characterized by a well-mixed water column and low light transmittance (Fig. S4). Although the Chl-a concentrations in the HTACW were similar to those in the Atchafalaya plume in the salinity range of 24 to 32 (Fig. 6b), the DO% was much lower in the HTACW (94.7±12.1 %, Fig. 6d). The $pCO_2$ in the HTACW (327.8±34.6 µatm) was higher than that in the Atchafalaya plume (288.7±43.7 µatm) at the same salinities (Fig. 6c), but the HTACW still acted as a weak sink for atmospheric CO$_2$ (-7.1±3.1 mmol C m$^{-2}$ d$^{-1}$, Fig. 6e). Similar to that in the Mississippi River channel, the two approaches for NCP estimation presented contrasting results in the HTACW: the negative NCP$_{O2Ar}$ (-39.2±14.0 mmol C m$^{-2}$ d$^{-1}$, Fig. 5a) suggests net heterotrophic condition while NCP$_{DO-incub}$ rates were positive (62.6±23.3 mmol C m$^{-2}$ d$^{-1}$, Fig. 5b).

4. Discussion

4.1 Comparison of NCP estimations

A comparison of NCP estimated from various methods should be interpreted with caution as each approach has its independent assumptions and limitations and refers to different temporal and spatial scale (Ulfsbo et al., 2014). However, applying multiple methods provides complementary information to better understand the processes affecting the estimation of the ecosystem metabolism.
**NCP from the DO incubation method:** The NCP\textsubscript{DO-incub} was estimated from the 24-hour DO changes in incubation bottles, which gives a daily NCP estimate for the plankton community at the sampling location. The DO incubation method is a direct measurement of NCP and is free from the influences of lateral advection and sediment metabolism. The NCP\textsubscript{DO-incub} thus equals the MLD-integrated NCP in the stratified regions (NCP\textsubscript{MLD} in Fig. 9a, c) or the water column-integrated NCP in the well-mixed regions (NCP\textsubscript{water} in Fig. 9b). However, there are uncertainties related to scaling from samples collected at discrete depths to integrated mixed layer NCP values. First, the scaling method used here assumes a homogenous distribution of respiration rate over the MLD. Second, we only measured GPP at one light level (50 \%) and we assumed that the GPP below 50 \% surface PAR was linearly scaled to \%PAR (Eq. 6 and Eq. 7). Similar assumptions for the Louisiana shelf were tested previously by Murrell and Lehrer, (2011) who found that single point measurements (vs. multi-point measurements in a layer) provided robust estimates of integrated rates. However, in the current study, the assumption has been further applied to shallow nearshore sites (< 10 m depth), which may exhibit greater heterogeneity in vertical PAR distributions due to the high algal biomass and suspended sediment particle concentrations. More importantly, for high-turbidity water samples (e.g., samples collected in the Mississippi River channel and in the HTACW), the incubated samples were not mixed in the same way as that in the natural environment and the sedimentation of particles in incubation bottles could alleviate the light limitation for phytoplankton. As a result, the gross primary production (GPP\textsubscript{int} in Eq. 8) could be overestimated and NCP\textsubscript{DO-incub} would not represent the true \textit{in situ} NCP in high-turbidity waters but as an overestimation.

**NCP from the O\textsubscript{2}/Ar method:** NCP\textsubscript{O2Ar} is derived from the air-sea biological oxygen flux (Eq. 4), which represents the exponentially weighted NCP over the past several residence times of O\textsubscript{2} (Kaiser et al. 2005; Teeter et al. 2018). When using the O\textsubscript{2}/Ar method to estimate NCP\textsubscript{MLD}, a key assumption is the negligible physical inputs to the mixed layer. However, this assumption can be invalid in the dynamic coastal environments. Recent studies have shown that entrainment and upwelling processes (mixing with O\textsubscript{2}-depleted subsurface water) can lead to significant underestimation in NCP\textsubscript{MLD} using the O\textsubscript{2}/Ar method, especially in coastal upwelling zones (Castro-Morales et al., 2013; Nicholson et al., 2012; Shadwick et al., 2015; Teeter et al., 2018). As most regions in our study were characterized by the persistent surface stratification (Figs. S2 and S3), the influences of sub-pycnocline (NCP\textsubscript{sub-MLD} in Fig. 9a, c) and benthic metabolisms (NCP\textsubscript{benthic} in Fig. 9a, c) on the surface O\textsubscript{2}/Ar ratio were expected to be minor. On the contrary, the surface O\textsubscript{2}/Ar ratio in the well-mixed nearshore regions (e.g., the
HTACW, Fig. S4) was affected by both water column (NCP\textsubscript{water}) and benthic metabolisms (NCP\textsubscript{benthic}) (Fig. 9b). Moreover, both Mississippi and Atchafalaya river end members were highly heterotrophic and the lateral transportation of this heterotrophic signal carried by river water (NCP\textsubscript{adv} in Fig. 9) should be considered. As it generally takes a few days for O\textsubscript{2} to become in equilibrium with the atmosphere (see the discussion below), NCP\textsubscript{adv} could play an important role affecting the O\textsubscript{2}/Ar ratio in the river channel and estuary where water transport speed was rapid (Fig. 9a, b). The influence of NCP\textsubscript{adv} decreased offshore and the impact of remote source water heterotrophy was negligible in most offshore regions where water residence time was sufficiently long (Fig. 9c). Therefore, NCP\textsubscript{O2Ar} represented the metabolic state of the water which was affected not only by local aquatic ecosystem (NCP\textsubscript{MLD} or NCP\textsubscript{water} in Fig. 9), but also by additional factors including NCP\textsubscript{benthic} and NCP\textsubscript{adv} (Fig. 9). Depending on the different mixing conditions in the nGOM, NCP\textsubscript{O2Ar} reflected 1) the combined result of NCP\textsubscript{MLD} and NCP\textsubscript{adv} in the stratified river channel and plume region; 2) the combined result of NCP\textsubscript{water}, NCP\textsubscript{benthic}, and NCP\textsubscript{adv} in the well-mixed nearshore waters (e.g., HTACW); 3) NCP\textsubscript{MLD} in the offshore stratified regions where riverine influence was minor. As NCP\textsubscript{benthic} only affected a small portion of the nearshore water in the Atchafalaya coastal region (Fig. S4), the NCP\textsubscript{O2Ar} measured in this study was mainly modulated by NCP\textsubscript{MLD} and NCP\textsubscript{adv}. Considering the nGOM as a whole, lateral advection of NCP\textsubscript{adv} can be considered as internal transport within the system given that the NCP\textsubscript{O2Ar} was measured with adequate spatial coverage. As a result, the NCP\textsubscript{O2Ar} measured in this study well represented the overall metabolic state of the surface water of the nGOM.

*NCP from the non-conservative changes in DIC and nutrients:* The NCP\textsubscript{DIC} and NCP\textsubscript{NO\textsubscript{x}} in the Mississippi plume reflected the average community production rate along the flow path during the river-ocean mixing process. There are several sources of uncertainty associated with the NCP estimated from the non-conservative mixing change in DIC and nutrients. First, errors in estimating water residence time and the changes in MLD over the transit time of the plume water lead to proportional errors in the calculation of NCP\textsubscript{DIC} and NCP\textsubscript{NO\textsubscript{x}} (Eq. 13 and Eq. 14). The plume water residence time is a function of river discharge and other physical conditions, it is therefore expected that using a set of past model-assessed \( \tau \) values probably would introduce the largest uncertainty in the estimation of NCP\textsubscript{DIC} and NCP\textsubscript{NO\textsubscript{x}}. Second, uncertainty may be caused by the changes in the concentrations of DIC and nutrients of the river end members. However, this uncertainty decreases with salinity (Huang et al., 2012) and was generally low in our study.
To better investigate the NCP rates estimated from different methods, we focused on the regions where NCP\textsubscript{O2Ar} and NCP\textsubscript{DO-incub} provided contrasting results: NCP\textsubscript{O2Ar} suggested heterotrophy in the Mississippi River channel and in the HTACW where positive NCP\textsubscript{DO-incub} rates were presented. The contrasting results of NCP\textsubscript{O2Ar} and NCP\textsubscript{DO-incub} can be mainly explained by the different spatial and temporal scales associated with the two methods responding to the mixing conditions. In the high-turbidity Mississippi River channel (light transmittance close to zero) and HTACW (light transmittance <20%), the GPP was strongly limited by light availability and the DO incubation method could significantly overestimate the in situ NCP due to the improved light environment in the incubation bottles. However, the measured community respiration rates (Resp\textsubscript{int} in Eq. 8) in the lower Mississippi River channel (14.0±0.8 mmol C m\textsuperscript{-2} d\textsuperscript{-1}) and in the HTACW (30.5±10.7 mmol C m\textsuperscript{-2} d\textsuperscript{-1}) were not able to fully account for the heterotrophy suggested by NCP\textsubscript{O2Ar} (-51.3±11.9 and -39.2±14.0 mmol C m\textsuperscript{-2} d\textsuperscript{-1} in the lower Mississippi River channel and HTACW respectively) even when the GPP was not taken into account. This indicates sources of heterotrophic signal other than the local community respiration in these two regions. In the stratified lower Mississippi River channel (Fig. 9a), the influence of lateral transportation of the heterotrophic river water from the upper river channel was significant because of the short water residence time (~1 day, Green et al., 2006). The heterotrophic condition in the lower Mississippi River channel could be attributed to the dominant influence of the heterotrophic NCP\textsubscript{adv} over the local biological production. In the vertically well-mixed HTACW (Fig. 9b), NCP\textsubscript{O2Ar} reflected the combined result of the water column community production, the lateral advection of CO\textsubscript{2}-rich Atchafalaya river water (NCP\textsubscript{adv}), and sediment metabolism (NCP\textsubscript{benthic}). High sediment oxygen consumption and bottom water community respiration rates were observed in the Atchafalaya River Delta Estuary (Roberts and Doty, 2015) and on the Louisiana continental shelf (Murrell and Lehrter, 2011; Murrell et al., 2013). These studies suggested that the total below-pycnocline respiration rates show low variability over a large geographic and temporal range in the nGOM (46.4 to 104.5 mmol O\textsubscript{2} m\textsuperscript{-2} d\textsuperscript{-1}). The negative NCP\textsubscript{O2Ar} observed in the HTACW by our study (-39.2±14.0 mmol C m\textsuperscript{-2} d\textsuperscript{-1}) agreed with the finding of Murrell et al., (2013) which showed shelf-scale net water column heterotrophy on the Louisiana shelf. This water column heterotrophy can be well explained by the combined results of NCP\textsubscript{water}, NCP\textsubscript{benthic} and NCP\textsubscript{adv}. The same logic can be applied to explain the net heterotrophy observed in the southwest part of the Atchafalaya plume with well-mixed water column (negative NCP\textsubscript{O2Ar} around 29.30° N, 93.50° W, Fig. 5a).
4.2 Controls on the surface NCP and CO$_2$ flux

As the underway O$_2$/Ar method provided the highest resolution NCP estimation coupled with $p$CO$_2$ measurement, NCP$_{O2Ar}$ was presented together with the CO$_2$ variables in the following sections to investigate the variability and controls of the metabolic balance. Nutrients, irradiance, and mixing were considered to be the major controlling factors of biological production in coastal waters of the nGOM (Lehrter et al., 2009; Lohrenz et al., 1999; Murrell et al., 2013; Turner and Rabalais, 2013). Here we use the results in the Mississippi plume (data averaged over increments of two salinity units, Fig. 7) to demonstrate the controlling mechanisms of the changes in surface NCP and CO$_2$ flux with the increasing salinity. There is an ecological gradient along the river-ocean mixing continuum: from turbid, eutrophic freshwater to clear, oligotrophic offshore oceanic waters (Fig. 7a). The freshwater input from the Mississippi River was characterized by strong heterotrophy with high DIC and $p$CO$_2$ supported by the decomposition of terrestrial organic carbon (Bianchi et al., 2010). Meanwhile, phytoplankton growth and production were limited by light availability in the high-turbidity Mississippi River channel despite the high nutrient concentration (Fig. 7a-c). The net heterotrophy of the water at the low salinity end and the corresponding CO$_2$ outgassing (Fig. 7d) were attributed to the terrestrial carbon input, light limitation on primary production, and short water residence time (Lehrter et al., 2009; Lohrenz et al., 1990; 1999; Roberts and Doty, 2015). While high CO$_2$ efflux was observed at low salinities, its contribution to the overall regional CO$_2$ flux was relatively small due to the limited spatial coverage of low salinity regions (Huang et al., 2015).

Due to the alleviation of light limitation in conjunction with persistence of riverine nutrient concentrations, Chl-a, DO% and NCP$_{O2Ar}$ all showed an increasing trend with salinity along the flow path of the Mississippi plume (Fig. 8). A positive correlation between the mean NCP$_{O2Ar}$ rates and Chl-a concentrations (Fig. 7b, d) was observed in the Mississippi plume ($r^2 = 0.75$, figure not shown) where light availability generally determined the onset of the biological growth and the river-borne nutrient loading set the magnitude of biological production (Fig. 7, Fig. 8). At intermediate salinities (15 to 30) in the Mississippi plume, there existed an “optimal growth region” where light and nutrient availability were both favourable for phytoplankton growth (Fig. 7) (Cloern et al., 2013; Demaster et al., 1996; Seguro et al., 2015). High NCP$_{O2Ar}$ (114.8±54.6 mmol C m$^{-2}$ d$^{-1}$) was observed in this optimal growth region corresponding to an oceanic CO$_2$ uptake of -13.5±5.3 mmol C
In high-salinity offshore water, phytoplankton growth and production were primarily limited by depleted nutrient concentration (Lehrter et al. 2009; Lohrenz et al. 1990; Lohrenz et al. 1999). Because of the minor terrestrial influence and low biological production, DO and $p$CO$_2$ in the offshore gulf water were close to equilibrium with atmosphere and NCP$_{O2Ar}$ and CO$_2$ flux were close to zero (Fig. 7).

The spatial variability of NCP and CO$_2$ flux in the nGOM are associated with the trajectory of the Mississippi and Atchafalaya plume as the surface biogeochemical variations are strongly affected by riverine influences. For instance, an unusually broad plume extension in the nGOM in March 2010, driven by upwelling favourable wind and high freshwater discharge, was associated with elevated chlorophyll concentrations and stronger biological CO$_2$ uptake (Huang et al., 2013). Modeling studies also suggested that NCP and CO$_2$ flux in the nGOM were susceptible to changes in river and wind forcing (Fennel et al., 2011; Xue et al., 2016). To better study the variability of surface NCP and CO$_2$ flux, further studies are needed to investigate how the seasonal and inter-annual variations in environmental conditions (freshwater discharge, riverine inputs of carbon and nutrients, wind forcing, coastal circulation etc.) affect the trajectory of the river plume and the biological processes therein.

### 4.3 Coupling between NCP and CO$_2$ flux

Overall, the surface water of the nGOM (93.00-89.25° W, 28.50-29.50° N) was estimated to be net autotrophic during our study period with an area-weighted mean NCP$_{O2Ar}$ rate of 21.2 mmol C m$^{-2}$ d$^{-1}$ and as a CO$_2$ sink of -6.7 mmol C m$^{-2}$ d$^{-1}$. When plotting the paired CO$_2$ flux and NCP$_{O2Ar}$ data (Fig. 10), most data collected in the lower Mississippi River channel fall in quadrant 2 suggesting net heterotrophy coupled with CO$_2$ outgassing to the atmosphere. The Mississippi plume and Atchafalaya plume exhibited opposite patterns with most data in these regions being in quadrant 4 (net autotrophy coupled with CO$_2$ uptake from the atmosphere). However, the data in quadrant 1 (autotrophic water as a CO$_2$ source observed near the Mississippi River mouth) and quadrant 3 (heterotopic water as a CO$_2$ sink in the HTACW) suggest decoupling between NCP$_{O2Ar}$ and CO$_2$ flux.

Here we use the 1-D model (Section 2.5) to investigate the relationship between NCP and air-sea gas fluxes of O$_2$ and CO$_2$. We calculated the re-equilibrium time for O$_2$ and CO$_2$ following the occurrence of 10 days biological modification: NCP was set as 50 (net autotrophy) or -50 (net heterotrophy) mmol C m$^{-2}$ d$^{-1}$ from days 0 to 10, and as zero after day 11 (Fig. S5). The
air-sea \(O_2\) flux rapidly reached a balance with the NCP-induced \(O_2\) changes for both the autotrophy and heterotrophy simulations with the re-equilibrium time for \(O_2\) for each estimation to be a few days (Fig. S5). Given the same environmental settings, the re-equilibrium time for \(CO_2\) was much longer (more than one month, Fig. S5). This is related to the relative slow air-sea \(CO_2\) exchange rate, and, more importantly the carbonate buffering system, i.e., the gas exchange-induced changes in aquatic \(CO_2\) are buffered by a much larger carbon pool of \(HCO_3^-\) and \(CO_3^{2-}\) (Zeebe and Wolf-Gladrow, 2001).

NCP affects air-sea gas exchange of \(CO_2\) through its influence on \(pCO_2\) in the surface water. Net autotrophy results in a net biological uptake of \(CO_2\) from the seawater (decrease in \(\Delta pCO_2(\text{sea-air})\) in Eq. 1) while net heterotrophy has the opposite effect. However, \(\Delta pCO_2(\text{sea-air})\) is not only affected by the \textit{in situ} NCP (\(\Delta pCO_{2\text{NCP}}\)), but also by the background level of \(\Delta pCO_2\) which is related to the preceding mixing and biological processes (\(\Delta pCO_{2\text{background}}\)): \(\Delta pCO_2(\text{sea-air}) = \Delta pCO_{2\text{background}} + \Delta pCO_{2\text{NCP}}\).

Therefore, local ecosystem net autotrophy (negative \(\Delta pCO_{2\text{NCP}}\)) does not necessarily result in \(CO_2\) uptake from the atmosphere (negative \(\Delta pCO_2(\text{sea-air})\)) if the NCP-induced \(pCO_2\) decrease occurs in a water with high heterotrophic background (highly positive \(\Delta pCO_{2\text{background}}\)). Similarly, net heterotrophy does not necessarily result in a \(CO_2\) outgassing if the source water is highly autotrophic.

In the simulation with time-dependent varying NCP rates (Fig. 11), we demonstrated how the preceding biological processes and the lingering background \(pCO_2\) affect the relationship between NCP and \(CO_2\) flux. The NCP rate in this simulation was set as 0 during days 0 to 30, changed to -50 mmol C m\(^{-2}\) d\(^{-1}\) (net heterotrophy) during days 31 to 60, then to 100 mmol C m\(^{-2}\) d\(^{-1}\) (net autotrophy) during days 61 to 90, and to -50 mmol C m\(^{-2}\) d\(^{-1}\) again during days 91 to 120 (Fig. 11a). Although NCP changed instantly, the backward exponentially weighted NCP derived from the bioflux of \(O_2\) (\(NCP_{O_2\text{Ar}}\) in Fig. 11a) lagged a few days behind NCP. After each change in NCP, the memory effect of the preceding NCP on DO tends to be small as the air-sea \(O_2\) exchange quickly balanced the NCP-induced \(O_2\) production or consumption within several days (Fig. 11b, c). On the contrary, the slow \(CO_2\) gas exchange and long re-equilibrium time of \(CO_2\) generated a significant memory effect of the preceding NCP on \(\Delta pCO_2(\text{sea-air})\) (Fig. 11b, c). The combined result of \textit{in situ} production and the lingering effect of background \(pCO_2\) thus resulted in the decoupling between \(NCP_{O_2\text{Ar}}\) and \(CO_2\) flux (data in quadrant 1 and quadrant 3 in Fig. 11d). One typical example is the results during days 91 to 120 (data in quadrant 3 in Fig. 11d): the strong preceding autotrophic production during days 61 to 90 led to highly negative \(\Delta pCO_{2\text{background}}\) (-315.5 \(\mu\)atm on day 90, Fig. 11c), which
makes the water acted as a CO$_2$ sink during days 91 to 120 (Fig. 11b) although the *in situ* heterotrophic NCP increased $p$CO$_2$ during this time period (Fig. 11c).

In summary, the decoupling between NCP and CO$_2$ flux can be the result of competing effect of $\Delta p$CO$_2$background and $\Delta p$CO$_2$NEP. In our observation, surface waters with oversaturated $p$CO$_2$ and positive NCP$_{O2Ar}$ (data in quadrant 1 in Fig. 10) were observed directly outside of the Mississippi River mouth. This is the region where *in situ* autotrophic biological productivity began to increase due to the alleviated light limitation, but the highly heterotrophic $\Delta p$CO$_2$background from the river channel made the water still acted as a CO$_2$ source. Decoupling was also observed in the HTACW where CO$_2$ uptake occurred under heterotrophic condition (data in quadrant 3 in Fig. 10). As discussed above, this phenomenon can be explained by *in situ* heterotrophy superimposed on surface water with low background $p$CO$_2$ resulting from the preceding autotrophic biological production.

**Conclusions**

During a spring cruise in the northern Gulf of Mexico in April 2017, we found encouraging agreement among NCP estimates from multiple approaches despite the different temporal and spatial resolutions and uncertainties associated with each approach. Our study showed that the DO incubation method represents the daily NCP by the local plankton community while the O$_2$/Ar method reflects the metabolic state of the water relating to both biological and physical processes over longer time scales. The DO incubation method may significantly overestimate NCP rates for high-turbidity water samples due to the improved light environment in the incubation bottles. The O$_2$/Ar method has the advantage being able to provide high-resolution NCP estimates matching the underway $p$CO$_2$ measurement, which provides more accurate estimation of the overall metabolic condition of the surface water of the nGOM and also allows a better examination on the NCP and CO$_2$ dynamics. The NCP$_{O2Ar}$ and CO$_2$ flux showed higher spatial variability on the inner and middle shelf which was strongly influenced by the Mississippi-Atchafalaya River system. Along the river-ocean mixing gradient, NCP$_{O2Ar}$ and CO$_2$ flux were characterized by 1) heterotrophy and CO$_2$ release at low salinities resulting from the decomposition of terrestrial carbon and light limitation on photosynthesis, 2) strong autotrophy and CO$_2$ uptake at intermediate salinities of 15-30 where light and nutrient are both favourable for phytoplankton growth, 3) close-to-zero NCP rate and CO$_2$ flux in the offshore seawater.
resulting from nutrient limitation. This study also demonstrated that, due to the slow air-sea CO$_2$ exchange and the buffering effect of the carbonate system, decoupling between NCP and CO$_2$ flux could be observed as the competing result of in situ biological production and the lingering effect of background $p$CO$_2$ of the source water.

**Data availability.**

Data of this study are available from the Biological and Chemical Oceanography Data Management Office: https://www.bco-dmo.org/project/751332.

**Author contributions**

Z-P.J., J.L., B.C., Z.O., N.H., M.K.S., and J.Z attended the nGOM cruise and all authors contributed to the data collection: O$_2$/Ar (Z-P.J., Z.O), incubation experiments (J.L.), $p$CO$_2$ (B.C.), DO (N.H.), DIC and TA (M.K.S., J.Z., Y.X.), nutrient (B.J.R.), and model and remote sensing (C.L.). W-J.C. designed and led the whole project. W-J.C. is the PI who supervised the sample analysis, data analysis and writing. Z-P.J. is the primary author while all co-authors were involved in discussion and writing by providing comments.

**Competing interests.**

The authors declare that they have no conflict of interest.

**Acknowledgement**

We thank the captain and crew of *RV Pelican* for their excellent work. We are grateful for the comments and suggestions from Isabel Seguro and the other anonymous reviewer which significantly improve the quality of this paper. This work was supported by the National Key Research and Development Program of China 2016YFA0601400, NSF OCE-1559279 and OCE-1760660. Zong-Pei Jiang and Junxiao Zhang acknowledge the support by China Scholar Council for supporting their one-year visit of the Cai laboratory during which the fieldwork was accomplished.

Figure

Fig. 1. Map and sampling sites in the northern Gulf of Mexico during the April 2017 cruise. The black dotted line is the cruise track along which the high-resolution underway measurements were made. The track in the Mississippi plume (purple line, 8-11 April) and in the Atchafalaya coastal regions (grey line, 15-17 April) are highlighted. Also shown are the 83 CTD sampling stations (hollow red squares), the 43 stations where light/dark bottle DO incubations were conducted (solid yellow squares), the 30 stations where non-conservative changes in DIC and NO₃ were used to estimate NCP rates (solid red triangles), and the 2 stations where the properties of river end members were measured (solid green diamonds). The vertical CTD profiles of the labelled stations were shown in the supplement.
Fig. 2. The distribution of (a) temperature, (b) salinity, (c) mixed layer depth (MLD), (d) light transmittance, (e) chlorophyll-a concentration (Chl-a), (f) oxygen saturation percentage (DO%), (g) partial pressure of CO$_2$ ($p$CO$_2$), and (h) biological-induced oxygen supersaturation ($\Delta$O$_2$/Ar) in the surface water of the nGOM.
Fig. 3. The underway measurements of (a) salinity and Chl-a, (b) DO% and $pCO_2$, and (c) NCP rates estimated from the O$_2$/Ar measurement (NCP$_{O_2Ar}$, grey circles). Also shown in panel c are the NCP rates estimated from the light/dark DO incubation (NCP$_{DO-incub}$, yellow squares), non-conservative changes in DIC (NCP$_{ADIC}$, red diamonds) or NO$_x$ (NCP$_{ANOX}$, green triangles). See Figure 1 for the cruise track in the Mississippi plume (8-11 April) and Atchafalaya coast (15-17 April). See Figure 5 for the positions of stations C10, A7, and X3 in the Mississippi plume.
Fig. 4. The fractional contribution of (a) the Mississippi River, (b) the Atchafalaya River, and (c) offshore surface water to the surface water of the nGOM estimated from the three end-member mixing model. The sub-regions shown in panels (a) and (b) are the Mississippi plume, the high-turbidity Atchafalaya coastal water (HTACW), and the Atchafalaya plume.
Fig. 5. The spatial variability of (a) \( \text{NCP}_{\text{O}_2} \), (b) \( \text{NCP}_{\text{DO-incub}} \), (c) \( \text{NCP}_{\Delta \text{DIC}} \), and (d) \( \text{NCP}_{\Delta \text{NO}_3} \). Noted that \( \text{NCP}_{\Delta \text{DIC}} \) and \( \text{NCP}_{\Delta \text{NO}_3} \) were only estimated in the Mississippi plume (panels c, d).
Fig. 6. The distribution of (a) light transmittance, (b) Chl-a, (c) $pCO_2$, (d) DO%, (e) $CO_2$ flux, and (f) NCP$_{O_2Ar}$ along the salinity gradient in different sub-regions. The dash lines in panels c to f are the atmospheric $pCO_2$ (405 µatm), DO% of 100 %, zero $CO_2$ flux, and zero NCP$_{O_2Ar}$ respectively.
Fig. 7. The distribution of (a) NO$_x$ and light transmittance, (b) Chl-a and DO%, (c) NCP estimated from various methods, and (d) NCP$_{O2Ar}$ and CO$_2$ flux along the salinity gradient in the Mississippi plume. Data in panels (a), (b), and (d) were averaged over increments of two salinity units.
Fig. 8. Scatter plots of (a) DIC and salinity, (b) NO\textsubscript{x} and salinity, and (c) the non-conservative changes in DIC (\(\Delta\text{DIC}_{\text{NCP}}\)) and NO\textsubscript{x} (\(\Delta\text{NO}_{\text{NCP}}\)) in the Mississippi and Atchafalaya plumes. The end member concentrations of the Mississippi river, the Atchafalaya River, and offshore gulf surface water are shown in panels (a) and (b) together with the conservative mixing lines.
Fig. 9. The differences in water column mixing conditions in the nGOM and their influences on NCP estimation. The dotted lines in panels (a) and (c) indicate the mixed layer depth. In the stratified lower Mississippi River channel (a) and the offshore stratified system (c), NCP\textsubscript{DO-incub} equals the in situ community production in the mixed layer (NCP\textsubscript{MLD}), while NCP\textsubscript{O2Ar} reflects the combined result of the NCP\textsubscript{MLD} and the influence of lateral advection of the river water (NCP\textsubscript{adv}). In the nearshore well-mixed shallow system (b), NCP\textsubscript{DO-incub} equals the water column community production (NCP\textsubscript{water}), while NCP\textsubscript{O2Ar} reflects the combined result of NCP\textsubscript{water}, NCP\textsubscript{benthic}, and NCP\textsubscript{adv}.

Note that the influence of NCP\textsubscript{adv} decreases offshore with the increasing water residence time.
Fig. 10. Scatter plot of NCP$_{O_{2}Ar}$ and CO$_2$ flux observed in the surface water of the nGOM. Positive NCP implies net autotrophy and negative CO$_2$ flux implies net oceanic CO$_2$ uptake from the atmosphere.
Fig. 11. Simulation of carbon and oxygen dynamics responding to time-dependent varying NCP rates and gas exchange using a 1-D model.

The variations of (a) NCP and exponentially weighted NCP (NCP_{O2Ar}), (b) air-sea CO$_2$ flux and O$_2$ flux, and (c) air-sea $p$CO$_2$ difference ($\Delta$pCO$_2$(sea-air)) and O$_2$ difference ($\Delta$O$_2$(sea-air)). (d) Scatter plot of CO$_2$ flux and NCP$_{O2Ar}$. Positive NCP implies net autotrophy and negative O$_2$ and CO$_2$ fluxes implies gas influxes into the water. See the text for details.
