10 **Abstract**

11 The frequency of extreme weather events, such as droughts, is assumed to increase leading to alterations of ecosystem
12 productivity and thus the terrestrial carbon cycle. Although grasslands typically show reduced productivity in response
13 to drought, their effects have been shown to vary quite dramatically. Here we tested in a two-year field experiment, if the
14 resistance and the resilience of grasses towards drought varies throughout a growing season and if the timing of drought,
15 thus, influences drought-induced reductions in annual net primary production (NPP) of grasses. For the experiment we
16 grew six temperate and perennial C3 grass species in a field as monocultures. The grasses were cut six times during the
17 growing season and subject to 10-week drought treatments that occurred either in the spring, the summer or the fall.
18 Across all species, drought-induced losses of productivity in spring were smaller (-20% to -51%) than in summer and fall
19 (-77% to -87%). This suggests a higher resistance to drought in spring when the productivity of the grasses is the highest
20 and plants are in their reproductive stage. After the release of drought, we found no prolonged suppression of growth. In
21 contrast, post-drought growth rates of formerly drought-stressed swards outperformed the growth rates of the control
22 swards. In 2014, the overcompensation after drought release was similar in all seasons, but differed in 2015. The strong
23 overcompensation of growth after drought release resulted in relatively small overall drought-induced losses of annual
24 ANPP (aboveground NPP) that ranged between -4% to -14% and were not affected by the timing of the drought event.
25 Our results show that (i) the resistance of growth rates in grasses to drought varies across the season and is positively
26 correlated with growth rates in the control, (ii) that positive legacy effects of drought indicate a high resilience of
27 temperate grasses to drought, and (iii) that the high resilience can compensate immediate drought effects on total annual
28 biomass production to a large extent.

29 **1. Introduction**

30 Temperate permanent grasslands cover 38% of the agricultural area of Europe and deliver essential ecosystem services
31 (Pilgrim et al., 2010; Suttie et al., 2005). These services include the production of fodder for livestock and the dairy
32 industry (Voigtländer and Boeker, 1987), the maintenance of biodiversity (Lachat et al., 2010), and the sequestration of
33 substantial amounts of carbon (Schulze et al., 2009). Climate projections forecast significant rainfall reductions in summer
34 for central Europe (CH2018, 2018; Fischer et al., 2015). Such drought periods will influence physiological processes of
35 ecosystems and consequently affect the ecosystem services that are delivered from permanent European grasslands
36 (Reichstein et al., 2013).

37 Numerous studies have attempted to quantify the effects of drought on grassland ecosystems in the past decade.
38 In general, these studies have confirmed that drought-induced water limitation typically leads to a reduction of net primary
39 productivity (NPP) (Gherardi and Sala, 2019; Wilcox et al., 2017; Wu et al., 2011). Importantly, however, these studies
40 have also shown that the response of ecosystems to experimental drought can vary quite dramatically (Gherardi and Sala,
41 2019; Gilgen and Buchmann, 2009; Grant et al., 2014; Hoover et al., 2014; Wilcox et al., 2017). Among others, the
42 drought response of grasslands has been shown to depend on the severity of the experienced drought (Vicca et al., 2012;
43 Wilcox et al., 2017), and important secondary factors such as the type of grassland affected (Byrne et al., 2013; Gherardi
44 and Sala, 2019; Sala et al., 2015; Wilcox et al., 2017), the intensity of land use (Vogel et al., 2012; Walter et al., 2012),
45 the plant functional composition (Gherardi and Sala, 2015; Hofer et al., 2016, 2017a; Mackie et al., 2018), or the
46 biodiversity of an ecosystem (Isbell et al., 2015; Kahmen et al., 2005; Wagg et al., 2017). These secondary factors that
47 affect the responses of terrestrial ecosystems to drought are just beginning to be understood (Reichstein et al., 2013; Wu
48 et al., 2011). Defining their impact on the drought response of terrestrial ecosystems is yet essential for quantitative
49 predictions of drought effects on the carbon cycle and for the ultimate inclusion of drought responses of terrestrial
50 ecosystems in coupled land surface models (Schiermeier, 2010; Smith et al., 2014).

51 Grassland ecosystems often show a pronounced seasonality, where plants undergo different phenological,
52 physiological, morphological or ontogenetic stages throughout a year (Gibson, 2009; Voigtländer and Boeker, 1987).
53 Temperate European grasslands for example, are highly productive early in the growing season during reproductive
54 growth, while they show much lower growth rates during vegetative stages in summer and fall (Voisin, 1988). Several
55 studies have addressed how the seasonal timing of drought affects aboveground NPP (ANPP) of North American C4
56 grasslands (Nippert et al., 2006; Petrie et al., 2018). It has been suggested that moisture availability during stalk production
57 of the dominant C4 grass species in mid-summer is particularly important for maintaining the annual productivity of these
58 grasslands (Denton et al., 2017; La Pierre et al., 2011). For C3 dominated temperate grasslands, this would imply that
59 spring, when grasses flower and have the highest growth rates, is the time when the productivity should be most
60 susceptible to drought and that productivity should be less prone to drought-induced losses in the summer and fall.

61 Empirical evidence how the seasonal timing of a drought event affects the productivity of temperate C3 dominated
62 grasslands is, however, missing.

63 The impact of drought on the annual NPP of ecosystems depends on the immediate effects of drought on
64 productivity (determined by the drought resistance of the ecosystem), but also on potential legacy effects that occur after
65 drought release (determined by the drought resilience of the ecosystem) (Sala et al., 2012; Seastedt and Knapp, 1993). In
66 particular, legacy effects of drought are a critical yet rarely explored component that can strongly affect the impact of
67 drought on the annual NPP of an ecosystem (Ingrisch and Bahn, 2018; Petrie et al., 2018; Sala et al., 2012). Previously it
68 was believed that the drought history (e.g. previous year annual precipitation deficit) of an ecosystem is crucial for the
69 annual NPP and that the magnitude of the drought history negatively influences current NPP (Mackie et al., 2018;
70 Reichmann et al., 2013; Sala et al., 2012; Yahdjian and Sala, 2006). In contrast, there is now increasing evidence that
71 drought stressed plants or ecosystems can respond to drought release also with an overcompensation of their physiological
72 activity or growth (Griffin-Nolan et al., 2018; Hofer et al., 2017a; Shen et al., 2016). Following an experimental drought,
73 tropical and temperate tree seedlings have, for example, exhibited higher net photosynthesis rates than seedlings that had
74 not experienced a drought event (Hagedorn et al., 2016; O'Brien et al., 2017). In grasslands, Hofer et al. (2016) recently
75 showed that formerly drought-stressed swards had a higher productivity in the post-drought period than non-stressed
76 control swards and that the species richness of a grassland contributes to this effect (Kreyling et al., 2017; Wagg et al.,
77 2017). Even across growing seasons it has been suggested that the previous growing season precipitation patterns can
78 have positive legacy effects on the current year productivity of ecosystems (Shen et al., 2016). As legacy effects can
79 either worsen or diminish immediate drought effects on annual NPP, their assessment is essential to determine if the
80 sensitivity of annual NPP to the timing of drought is driven by the resistance or resilience of the system (Petrie et al.,
81 2018; Shen et al., 2016). This requires, however, a detailed analysis of not only annual NPP, but the assessment of biomass
82 increase (i.e. productivity) during and after the release of a drought event.

83 In the work that we present here, we experimentally assessed if the drought response of the annual NPP of six
84 different grasses that are common in temperate C3 grasslands depends on the timing of the drought event in the growing
85 season. To do so, we determined the drought resistance and resilience for these grasses in different times of the growing
86 season. Specifically, we tested in our study,

- 87 i) if the timing of a drought event within the growing season (e.g. spring, summer, fall) has an effect on
88 the immediate aboveground productivity reduction – i.e. the resistance of an ecosystem,
- 89 ii) if the timing of a drought event within the growing season affects the resilience of an ecosystem, and
- 90 iii) how the combination of resistance and resilience in different times of the growing season impact the
91 annual aboveground productivity of drought-stresses C3 grasses.

92

93 **2. Materials and methods**

94 **2.1 Research site**

95 The experiment was performed in the years 2014 and 2015 near Zurich, Switzerland (47°26'N, 8°31'E, altitude: 490 m
96 a.s.l., mean annual temperature: 9.4°C, mean annual precipitation: 1031 mm) on an eutric cambisol soil. For the
97 experiment, we established six perennial C3 grass species in monoculture that are commonly used in agricultural practice
98 in August 2013 on 96 plots (3 × 5 m). The plants were sown on a highly productive field that yields typically around 12
99 t grass dry matter per year and hectare (i.e. 1200 g m⁻²). The establishment followed the basic procedures of sowing
100 permanent highly productive grasslands, where before sowing, the existing vegetation at the site (which was a winter
101 wheat) was plowed. Establishment of the grasses in the growing season before the experiment started followed best
102 practice and guaranteed full establishment of the swards (including vernalisation during winter) and full productivity in
103 the following year. The six grasses were *Lolium perenne* L. early flowering (LPe; cultivar 'Artesia'), *Lolium perenne* L.
104 late flowering (LPl; cultivar 'Elgon'), *Dactylis glomerata* L. early flowering (DGe; cultivar 'Barexcel'), *Dactylis*
105 *glomerata* L. late flowering (DGl; cultivar 'Beluga'), *Lolium multiflorum* Lam. var *italicum* Beck (LM; cultivar 'Midas'),
106 and *Poa pratensis* L. (PP; cultivar 'Lato'). Phosphorous, potassium and manganese were applied following national Swiss
107 fertilization recommendations for intensely managed grasslands at the beginning of each growing season (39 kg P ha⁻¹,
108 228 kg K ha⁻¹, 35 kg Mg ha⁻¹). In addition, all plots received the same amount of mineral N fertilizer as ammonium-nitrate
109 (280 kg N ha⁻¹, divided into six applications per year). The solid N fertilizer was applied at the beginning of the growing
110 season (80 kg N ha⁻¹) and after each of the first five cuts (40 kg N ha⁻¹ each time).

111

112 **2.2 Experimental design**

113 Each of the six grass species was subject to four treatments: one rain-fed control and three seasonal drought treatments
114 (spring, summer, fall) (see Fig. 1). We used a randomized complete block design with four blocks representing the four
115 replicates. Each block contained all the 24 plots (six species times four treatments) fully randomized. A drought treatment
116 lasted for ten weeks. Drought was simulated using rainout shelters that excluded rainfall completely on the treatment
117 plots. The rainout shelters were tunnel-shaped and consisted of steel frames (3 × 5.5 m, height: 140 cm) that were covered
118 with transparent and UV radiation transmissible greenhouse foil (Lumisol clear, 200 my, Hortuna AG, Winikon,
119 Switzerland). To allow air circulation, shelters were open on both opposing short ends and had ventilation openings of
120 35 cm height over the entire length at the top and the bottom at both long sides. Gutters were installed to prevent the water
121 from flowing onto adjacent plots, and a 0.75 m boarder zone at each plot was not considered for measurements to prevent
122 a possible effect of lateral water flow in the soil. These shelters and plot design had previously been successfully used in
123 other grassland-drought experiments (Hofer et al., 2016, 2017a, 2017b). Rain-fed controls were subject to the natural
124 precipitation regime. However, when soil water potential (Ψ_{soil}) sank below -0.5 MPa due to naturally dry conditions,

125 control plots were additionally watered with 20 mm of water (300 l per plot). Watering happened once on June 16th and
126 17th 2014 and three times in 2015 (7.7., 14.7., 11.8.).

127

128 **2.3 Environmental measurements**

129 Relative humidity and air temperature were measured hourly at the field site using VP-3 humidity, temperature and vapor
130 pressure sensors (Decagon Devices, Inc., Pullman, WA, USA). Measurements were conducted in control and treatment
131 plots under the rainout shelters (n=2). Information on precipitation and evapotranspiration was provided by the national
132 meteorological service stations that were in close proximity of our research site (average of the two surrounding
133 meteorological stations Zurich Affoltern in 1.4 km distance and Zurich Kloten in 4.5 km distance). Ψ_{Soil} was measured
134 in 10 cm depth on an hourly basis using 32 MPS-2 dielectric water potential sensors (Decagon Devices, Inc., Pullman,
135 WA, USA). The soil water potential sensors were evenly distributed over the field and treatments. Daily means of all
136 measurements were calculated per treatment, but across grasses since no grass-specific alterations in Ψ_{Soil} were expected
137 (Hoekstra et al., 2014) or measured (n=8).

138

139 **2.4 Harvests**

140 Aboveground biomass was harvested six times per year in five-week intervals in 2014 and 2015, resulting in six growth
141 periods per year (see Fig. 1). Aboveground biomass was also harvested once in spring 2016. Such a high frequency of
142 harvests is typical for highly productive grasslands used for fodder production. For the purpose of our study this high-
143 resolution biomass sampling allows the analyses of the immediate drought effects and the impacts of drought that occur
144 after the release of drought on productivity. The harvests were synchronized with the drought treatments and occurred
145 five and ten weeks after the installation of the shelters on a respective treatment. For the harvest, aboveground biomass
146 was cut at 7 cm height above the ground and harvested from a central strip (5 × 1.5 m) of the plot (5 × 3 m) using an
147 experimental plot harvester (Hege 212, Wintersteiger AG, Ried/I., Austria). The fresh weight of the total harvest of a plot
148 was determined with an integrated balance directly on the plot harvester. Dry biomass production was determined by
149 assessing dry weight – fresh weight ratios of the harvested biomass. For this a biomass subsample was collected for each
150 plot and the fresh and dry weight (dried at 60°C for 48 h) were determined. After the harvest of the aboveground biomass
151 in the central strip of a plot, the remaining standing biomass in a plot was mowed 7 cm above the ground and removed.

152

153 **2.5 Roots**

154 Belowground biomass of four grasses (DGe, DGI, LPe and LPI) was harvested six times per year, at the end of each
155 drought period and six to eight weeks after drought release, from the respective treatment and control plots using a manual
156 soil auger with a diameter of 7 cm. For each plot samples of the upper 14 cm soil were taken from two different spots

157 (one sample directly from a tussock and one from in between tussocks) and pooled as one sample per plot. All samples
158 were washed using a sieve with a mesh size of 0.5 cm × 0.5 cm and weighed after drying (at 60°C for 72 h).

159

160 **2.6 Determining drought impacts on productivity**

161 In order to allow the comparison of grassland productivity in the different treatments across the two years we standardized
162 the productivity that occurred in between two harvest periods (i.e. during five weeks) for growth related temperature
163 effects and calculated temperature-weighted growth rates for each of the six grasses (DMYTsum, see Menzi et al. (1991)).
164 For this purpose, we determined temperature sums of daily mean air temperature above a baseline temperature of 5°C
165 (Tsum) for each growth period (i.e. 5 weeks prior to harvest). Dry matter yield (DMY) of a given harvest was then divided
166 by the temperature sum of the corresponding time period to obtain temperature-weighted growth rates (henceforth referred
167 to simple as growth rate):

168

$$169 \quad \text{DMYTsum} = \text{DMY}(\text{g m}^{-2})/\text{Tsum}(\text{°C}). \quad \text{Eq. (1)}$$

170

171 To determine the absolute change of growth (ACG) of a drought treatment on aboveground growth rate we calculated the
172 difference between temperature-weighted growth rates in a drought treatment (drt) and the corresponding control (ctr):

173

$$174 \quad \text{ACG} = \text{DMYTsum}(\text{drt}) - \text{DMYTsum}(\text{ctr}). \quad \text{Eq. (2)}$$

175

176 To determine the relative change of growth (RCG) due to drought, we calculated percentage change of temperature-
177 weighted growth rates:

178

$$179 \quad \text{RCG} = 100 \times (\text{DMYTsum}(\text{drt})/\text{DMYTsum}(\text{ctr}) - 1). \quad \text{Eq. (3)}$$

180

181 Annual ANPP as an average of the different grasses was determined by adding up the dry matter yields of the six harvests
182 of a growing season. These data were not temperature-corrected (DMY).

183

184 We further calculated the sensitivity (S) of annual ANPP to the different drought treatments to quantify the response
185 relative to the amount of precipitation change, as suggested by previous studies (Huxman et al., 2004; Knapp et al., 2017;
186 Wilcox et al., 2017):

187

$$188 \quad S = (\text{DMY}(\text{ctr}) - \text{DMY}(\text{drt})) / (\text{PPT}(\text{ctr}) - \text{PPT}(\text{drt})) \quad \text{Eq. (4)}$$

189

190 with PPT being the amount of precipitation in the treatment (drt) and control (ctr).

191

192 2.7 Data analysis

193 Relative and absolute changes in DMYTsum due to drought, the season of drought, and the tested grasses were analyzed
194 using linear mixed-effects regression (Pinheiro and Bates, 2000). Temperature-weighted growth rate (DMYTsum) was
195 regressed on the fixed variables season (factor of three levels: spring, summer, fall), drought (factor of two levels: control,
196 drought treatment) and grass (factor of six levels: LPe, LPI, DGe, DGI, LM, PP), including all interactions. To account
197 for repeated measurements of the control plots over time (as the control for every seasonal drought treatment was the
198 same), plot was specified as a random factor, thereby accounting for potential correlation of DMYTsum over time.
199 DMYTsum was natural log-transformed prior to analysis to improve homogeneity and normal distribution of residual
200 variance. This transformation also implies that the regressions provide the inference to relative changes in DMYTsum,
201 namely RCG. A temporal compound symmetry correlation structure was initially imposed on the residuals, yet, it turned
202 out that the estimated correlation parameter was very small. A likelihood ratio test indicated its non-significance ($p > 0.5$)
203 and it was finally omitted. However, inspection of residuals revealed clear differences in their variance among seasons
204 and control and drought plots, and the residual variance parameter was defined as $\text{Var}(e_{jk}) = \sigma^2 \delta_{jk}^2$, with δ being a ratio to
205 represent $j \times k$ variances, one for each of three seasons j under control and drought conditions k (Pinheiro and Bates,
206 2000). The R^2 of explained variance of fixed effects was computed following Nakagawa and Schielzeth (2013). This
207 model was applied to DMYTsum at each second growth period under drought and the second post-drought growth period
208 in 2014 and 2015.

209 Root dry weight was analyzed in a similar way, i.e. it was natural log-transformed prior to analyses and the same
210 explanatory factors were applied except that the factor grass had only four levels (only LPe, LPI, DGe and DGI measured).
211 Here, estimation of a single residual variance parameter e_i was sufficient to fulfill the model assumptions.

212 Annual ANPP was analyzed by one-way analysis of variance. The first factor season-treatment consisted of the
213 four levels control, spring drought, summer drought, and fall drought. The second factor grass consisted of six levels,
214 representing the six grasses.

215 All statistical analyses were done using the statistical software R, version 3.5.1 (R Foundation for Statistical
216 Computing, Vienna, Austria, 2018). Graphics were implemented with the package *ggplot2*, version 2.1.0 (Wickham,
217 2016).

218 **3. Results**

219 **3.1 Precipitation, evapotranspiration and soil water potential**

220 Over the entire growing season, the year 2015 was exceptionally dry, while 2014 showed normal climatic conditions for
221 the experimental site. The difference between rainfall (634 and 568 mm for 2014 and 2015, respectively) and
222 evapotranspiration (356 and 447 mm for 2014 and 2015, respectively) was 278 mm in 2014 and only 121 mm in 2015
223 for the unsheltered control plots. The shelter periods reduced the total annual precipitation in the different treatments
224 between 17.9 % and 37.0 % and the precipitation of the growing season (duration of the experiment, approx. March –
225 November) by between 23.1 % and 45.8 % (see Table 1).

226 In 2014 Ψ_{Soil} was severely reduced in the drought treatments and reached values around the permanent wilting
227 point (-1.5 MPa) for the entire second half of the sheltered periods in all treatments (spring, summer, fall) (Fig. 2b-e,
228 Table 2). Due to low rainfall in June 2014, Ψ_{Soil} dropped not only in the sheltered summer drought treatment, but also in
229 the control and the fall drought treatment (that was not yet sheltered). Ψ_{Soil} recovered in the treatment plots after each
230 sheltered period and reached Ψ_{Soil} values comparable to the ones in the control plots. Because of the lack of rain in June
231 2014, the full rewetting of the spring drought treatment occurred only in the second post-drought growth period after the
232 spring drought shelter period, while after the summer drought treatment rewetting occurred already in the first post-
233 drought growth period.

234 In 2015, drought treatments reduced Ψ_{Soil} in all seasons (Fig. 2g-k). However, an intense rain event caused some
235 surface runoff in the field on May 1st 2015, which partly interrupted the spring drought treatment. Still, for the second
236 growth period of the spring drought treatment of 2015 the median of Ψ_{Soil} was at -0.77 MPa, a value comparable to that
237 of the second growth period of the summer drought treatment (-0.83 MPa) (Table 2). In 2015 Ψ_{Soil} reached lower values
238 during the shelter period in the fall treatment than during the shelter period in the spring and summer treatments. Due to
239 a lack of rain in 2015, Ψ_{Soil} recovered only partly after the end of the shelter period in the spring and summer drought
240 treatments and remained significantly below that of the control plots for both post-drought growth periods (Table 2).
241 Watering of the control plots during natural dry conditions lead to quick increases in Ψ_{Soil} to values close to saturation
242 (=0 MPa).

243 Daily mean air temperature under the rainout shelters was between 2.9°C lower and 3.5°C higher than in the
244 control.

245

246 **3.2 Varying growth rates throughout the growing season**

247 The temperature-weighted growth rates of the investigated six grasses in the control plots showed a clear seasonal pattern
248 (Fig. 3a). In both years, it was highest during the second growth period in spring and sharply declined to values that were

249 two- to eight-fold smaller in summer and fall. Except for the second growth period growth rates of the grasses were lower
250 in 2015 than in 2014. Root biomass increased towards summer and slightly decreased after summer in 2014 (Fig. 3b).

251

252 3.3 Seasonality of drought resistance

253 The growth rates of the six grasses were barely affected by the exclusion of rain during the first five weeks of sheltering
254 (Fig. 4). However, during the second sheltered growth period (weeks six to ten), the drought treatments strongly reduced
255 temperature-weighted growth rates in all seasons, in both years, and in relative and absolute terms (Figs. 4, 5 and 6, Table
256 3). In both years, the relative drought-induced changes in growth rates compared to the controls were smallest in spring
257 (2014: -51%, 2015: -20%) and clearly larger in summer (2014: -81%, 2015: -85%) and fall (2014: -77%, 2015: -84%)
258 (Fig.4a, Table 3; season \times treatment $p < 0.001$). As such, the drought resistance of temperate grasses throughout the
259 growing season was largest in spring and positively correlated with their productivity (Fig. 5). This pattern was generally
260 observed for all six grasses tested (Fig. 6a) even though there was a significant season \times treatment \times grass interaction
261 (Table 3). In 2014 this interaction mainly derived from DGI and PP showing an exceptionally large drought induced
262 growth reduction in fall. In 2015 it was explained by an especially low drought response of DGI in spring and strong
263 responses of DGI in summer and LPe and PP in fall (Fig. 6a).

264 In 2014 the absolute drought-induced reduction of growth across all six grasses was largest in spring (-0.5 g m^{-2}
265 $^{\circ}\text{C}^{-1}$), followed by summer ($-0.4 \text{ g m}^{-2} \text{ }^{\circ}\text{C}^{-1}$) and was lowest in the fall ($-0.1 \text{ g m}^{-2} \text{ }^{\circ}\text{C}^{-1}$) (Fig. 4b). Likewise, in 2015 the
266 absolute reduction of the growth rate in the drought treated plots was largest across the six grasses in spring (-0.2 g m^{-2}
267 $^{\circ}\text{C}^{-1}$), but slightly lower in summer ($-0.1 \text{ g m}^{-2} \text{ }^{\circ}\text{C}^{-1}$) and fall ($-0.1 \text{ g m}^{-2} \text{ }^{\circ}\text{C}^{-1}$).

268 The average standing root biomass across four of the grasses was not significantly affected by any of the drought
269 treatments of 2014 (Fig. 7).

270

271 3.4 Seasonality of post-drought resilience

272 When compared to corresponding controls, relative (and absolute) changes in temperature-weighted growth rates after
273 drought release showed positive treatment effects in 2014 (Fig. 8, Table 4). Across all six grasses, the relative increases
274 in post-drought growth rates were 41% after the spring drought treatment, 31% after the summer drought treatment and
275 53% after the fall drought treatment, and did not differ among the seasons (Table 4; season \times treatment $p = \text{n.s.}$). In 2015,
276 the relative increases in post-drought growth rates were 5% after the spring drought treatment, 15% after the summer
277 drought treatment and 52% after the fall drought treatment, and did differ among the seasons (Table 4; season \times treatment
278 $p < 0.001$). Increased growth rates were also observed in the first harvest in 2015 and 2016 for all the plots that had received
279 a drought treatment in 2014 and 2015, respectively (Fig. 4). In this first harvest of 2015, growth rate increases were 110%

280 after the spring, 36% after the summer and 53% after the fall drought treatments of 2014. In the first harvest of 2016,
281 growth rate increases were 10% after the spring, 31% after the summer and 51% after the fall drought treatments of 2015.

282 When compared across the different grasses, the only grass that tended to have a weaker resilience (lower or no
283 increase of growth rate during post-drought) was LM (Fig. 8); but there was no significant difference among the grasses
284 (Table 4; treatment x grass $p=n.s.$). In 2015 again LM showed the weakest resilience of all the grasses after all drought
285 treatments, the effect being significant (Table 4; treatment x grass $p<0.001$).

286 Root dry weight of the treatment plants showed no alterations in growth compared to the control in either of the
287 post-drought periods (Fig. 7).

288

289 3.5 *Effects of seasonal drought on annual biomass production*

290 The cumulative annual aboveground biomass production (i.e. annual ANPP) of the controls averaged across all six grasses
291 differed strongly between the two years (Fig. 9a), with 2014 ($1303 \text{ g m}^{-2} \text{ a}^{-1}$) being 37% more productive than 2015 (949
292 $\text{g m}^{-2} \text{ a}^{-1}$). The strong reduction in biomass production in 2015 was most probably related to the naturally occurring lack
293 of rain in summer and fall (Fig 2). This is evident from the two spring growth periods being equally productive in the
294 unsheltered plots (control, summer and fall drought) in 2015 and in 2014 (Fig. 9a). The annual ANPP of the treatments
295 was significantly different from control in both years. In 2014, the largest drought effect on the annual ANPP across all
296 grasses resulted from the summer treatment, which reduced productivity significantly by 14% (185 g m^{-2}) compared to
297 the control. Spring and fall drought treatments in 2014 resulted in a non-significant 4% (53 g m^{-2}) and 6% (74 g m^{-2})
298 reduction of annual ANPP across all grasses, respectively. In 2015, drought treatments in the summer and fall significantly
299 caused a 10% and 11% reduction of annual ANPP across all grasses (-97 g m^{-2} and -105 g m^{-2}), respectively, while the
300 spring drought treatment reduced annual ANPP across all grasses by only 4% (34 g m^{-2}), which was not significant (Fig.
301 9a).

302 The sensitivity of annual ANPP to drought differed between the treatments in both years of the experiment. In
303 2014, the annual ANPP was most sensitive to drought in the summer, while annual ANPP was less sensitive to rainfall
304 reduction in the spring but also fall (Fig. 9b). In 2015, the sensitivity increased within the growing season so that annual
305 ANPP was least sensitive to spring drought and most sensitive to fall drought (Fig. 9b).

306

307 **4. Discussion**

308 In our study we experimentally assessed if the drought resistance and resilience of six different temperate perennial C3
309 grasses varies throughout the growing season and if the timing of a drought event, thus, has an influence on drought
310 induced reductions in annual NPP of these grasses. All six temperate grasses showed a clear seasonal pattern of drought
311 resistance in both years. The drought-induced reduction of growth was smaller under spring drought (-20% and -51% for
312 the two years) than under summer and fall droughts (between -77% and -87%). Thus, the investigated grasslands were
313 more resistant to drought in the spring when productivity of temperate grasses is generally the highest and they were least
314 resistant in summer and fall, when their productivity is much lower. Moreover, the examined grasslands did not show any
315 negative legacy effects such as a prolonged suppression of growth after rewetting following the end of the drought
316 treatments. In contrast, after the release of drought, temperature-weighted growth rates of the grasses in the treatment
317 plots surprisingly outperformed the growth rates of the grasses in the controls for extended periods of time. This suggests
318 a high resilience of all six grasses that we investigated. As a consequence of the high resilience, the seasonal drought
319 treatments resulted in only moderate drought-induced reductions in annual aboveground NPP between -4% to -14% -
320 despite the strong immediate effects of drought - and no clear effects of the timing of drought on annual NPP were
321 detected. With this our study shows (i) that the resistance of growth rates in different grasses to drought varies throughout
322 the growing season and is positively correlated with growth rates in the control, (ii) that positive legacy effects of drought
323 on plant productivity indicate a high resilience of temperate C3 grasses throughout the entire growing season, and (iii)
324 that the high resilience can strongly compensate for immediate seasonal drought effects on productivity, resulting in total
325 annual NPP that is only marginally reduced in the drought treated plots compared to the controls.

326

327 **4.1 Differences in the climatic conditions between the two years**

328 While the first experimental year (2014) was characterized by more or less normal climatic and thus growth conditions,
329 the summer of 2015 was exceptionally dry in all of central Europe (Dietrich et al., 2018; Orth et al., 2016). These
330 conditions led to a reduction of the annual NPP of the control plots by 37% in 2015 compared to 2014 (Fig. 9a). The lack
331 of rain in the second half of the 2015 growing season i.e. between the third harvest in June and the last harvest in October
332 (Fig. 2) was of importance for our experiment, especially for the response of the treatments during the recovery phase
333 after the removal of the shelters. In this period, the amount of rainfall was only 153 mm in 2015 while it was 405 mm in
334 2014. Thus, positive legacy effects directly following drought treatments were much smaller or absent following the
335 spring and summer treatments in 2015 due to a missing rewetting (Figs. 2, 4 and 8). Yet, strong positive legacy effects in
336 response to the 2015 treatments were observed in the first harvest of 2016 when the experimental site was fully rehydrated.
337 This highlights the general occurrence of positive drought legacy effects in the investigated grasslands once the soil
338 moisture has recovered from the drought treatments.

339 Intense rains between the first and second harvest of the year 2015 caused some water flow into the treatments.
340 This resulted in a partial reduction of drought stress in the treatment plots (Fig. 2h). Yet, the median of the soil water
341 potential was still clearly reduced in the treatment plots compared to the control and, consequently, we observed a
342 reduction of growth rates in the second spring harvest in 2015 despite this event (Figs. 4, 6). We therefore conclude that
343 the partial reduction in drought stress did weaken the immediate drought response during the growth period concerned,
344 but that this does not question the overall drought responses of the grasslands that we report here.

345

346 **4.2 Grasses were most resistant to drought in spring, the most productive part of the growing season**

347 Previous studies have indicated that the timing of drought is relevant for the reduction of annual NPP of ecosystems
348 (Bates et al., 2006; Denton et al., 2017; La Pierre et al., 2011; Nippert et al., 2006). It has been argued that the variable
349 drought sensitivity of ecosystems throughout the growing season could be linked to different phenological stages of
350 dominant plant species, where plants in reproductive stages and periods of high growth are particularly susceptible to
351 drought (Bates et al., 2006; Craine et al., 2012; Dietrich and Smith, 2016; Heitschmidt and Vermeire, 2006; O'Toole,
352 1982). We found, however, that relative reductions in temperature-weighted growth rates were lowest in the spring
353 treatments 2014 and 2015 as compared to the summer and fall treatments. The highest resistance of plant growth rates to
354 drought occurred, thus, when the plants showed the highest growth rates in the control and when the investigated grasses
355 were in their reproductive stages (Fig. 5). With this, our findings are in contrast to previous studies that have suggested
356 temperate grasslands and crops to be particularly susceptible to drought early in the growing season when their growth
357 rates are the highest and plants are in reproductive stages (Bates et al., 2006; Craine et al., 2012; Dietrich and Smith,
358 2016; Heitschmidt and Vermeire, 2006; Jongen et al., 2011; O'Toole, 1982; Robertson et al., 2009). Our study does
359 support, however, findings of El Hafid et al. (1998) and Simane et al. (1993), who detected that spring droughts have the
360 least impact on annual productivity of wheat. Importantly, most of the previous studies that have reported the effects of
361 drought timing on grasslands or other ecosystems report effects on annual NPP but have not differentiated immediate and
362 long-term legacy effects of drought events as we did in our study. As drought impacts on annual NPP combine immediate
363 and post drought legacy effects, it is difficult to directly compare the results we present here on variably seasonal drought
364 resistance of temperate C3 grasses to previous work reporting the influence of drought timing on annual NPP.

365 One possibility for the higher drought resistance of grasses during spring is that grasses invest more resources
366 towards the stress resistance of their tissue in this part of the growing season when they have not only the largest growth
367 rates, but also reproduce. Such a resource allocation strategy could allow drought stressed grasses to remain
368 physiologically active in this critical part of the growing season. Osmotic adjustment is one mechanism that reduces the
369 effects of drought on the physiological performance of the plant (Sanders and Arndt, 2012). This is achieved through the
370 active accumulation of organic and inorganic solutes within the plant cell. Thus, osmotic potential increases and the plant

371 can withstand more negative water potentials in the cell while maintaining its hydraulic integrity (Sánchez et al., 1998).
372 Santamaria et al. (1990) found that early- and late flowering cultivars of *Sorghum bicolor* L. developed a different pattern
373 of osmotic adjustment (continuous increase of osmotic adjustment vs. first increase and later decrease of osmotic
374 adjustment), hinting that drought tolerance may vary between seasons. In a companion paper we report physiological data
375 for the six grasses from the same experiment. We show that at a given soil water potential, foliar water potentials were
376 less negative and stomatal conductance was higher in plants drought stressed in the spring compared to plants drought
377 stressed in the summer or fall (Hahn et al. in prep). This suggests indeed that for a given drought level, grasses remain
378 physiologically more active in the spring than in the summer or fall. The exact physiological mechanisms that explain the
379 higher drought resistance of the investigated grasslands in the spring and their higher drought susceptibility in the summer
380 and fall remain yet unknown and require further detailed ecophysiological and biochemical assessments.

381 An alternative explanation for different immediate drought effects on growth rates throughout the growing
382 season are experimental artefacts causing different experimentally induced drought severities throughout a growing
383 season. This could be by either residual moisture dampening the experimentally induced drought more in the spring than
384 in the summer or fall. Alternatively, higher evaporative demand of the atmosphere in the summer compared to the spring
385 or fall could have enhanced experimentally induced drought effects in the summer. De Boeck et al. (2011) explain for
386 example the higher drought susceptibility of growth in three herbs in the summer compared to spring by a higher
387 evaporative demand of the atmosphere in the summer compared to spring or fall. In our study, however, soil water
388 potential data indicate that ten weeks of drought treatment reduced plant available water in the soil to mostly equal levels
389 in spring, summer and fall (Fig. 2). In addition, we found only small differences in median VPD between the spring,
390 summer and fall drought treatment period (Fig. 2). This suggests that stronger drought stress in summer and fall compared
391 to spring cannot explain alone the different resistances of plant growth to drought throughout the growing season. Along
392 these lines, Denton et al. (2017), who performed a similar experiment as we report here but in a C4 grassland in North
393 America, also did not find that these seasonal differences in the experimentally induced drought severity are the reason
394 for variable drought effects on the growth rates throughout the growing season.

395

396 **4.3 No increased root biomass in the top soil layer**

397 In the entire experiment, root biomass increased only in one out of the four investigated grasses (DGe) in response to
398 drought in summer as well as in the post-summer drought period. This confirms the findings of Byrne et al. (2013),
399 Denton et al. (2017) and Gill et al. (2002), who did not find any changes in belowground biomass in response to drought.
400 In a similar setting, Gilgen and Buchmann (2009) found no changes in belowground biomass to simulated summer
401 drought in three different temperate grassland sites (from lowland to alpine grassland). While Denton et al. (2017) ascribe
402 the missing drought response in belowground biomass to modest precipitation alterations in their experiment, we can

403 exclude this a factor in our experiment since the soil water potential under drought was significantly reduced compared
404 to the soil water potential in the controls in every season. Contrary to that, several studies have shown that drought can
405 maintain or increase root growth while inhibiting shoot growth (Davies and Zhang, 1991; Hofer et al., 2017a; Saab et al.,
406 1990). In an experiment by Jupp and Newman (1987), *L. perenne* increased lateral root growth under low Ψ_{soil} indicating
407 an increased investment in root growth under water limited conditions. In our experiment the *L. perenne* grasses did not
408 show a trend towards increased investment in root growth, neither during drought nor after drought-release, contradicting
409 the results of Jupp and Newman (1987). Such differences in the response of root biomass in different studies as described
410 above may derive from the soil layer that was investigated. Hofer et al. (2017a) have shown that the response of root
411 growth into ingrowth bags depended on the soil depth: root growth of *L. perenne* decreased in the top soil layer (0-10
412 cm), but increased in deeper soil layers of 10-30 cm. Thus, the superficial root sampling (0-14 cm) in our experiment
413 might mask increased root growth in deeper soil.

414

415 **4.4 Positive legacy effects of drought periods**

416 Several previous studies have suggested that drought events can lead to negative legacy effects on the productivity of
417 ecosystems (Petrie et al., 2018; Reichmann et al., 2013; Sala et al., 2012). We found, however, that growth rates of
418 previously drought-stressed plots were significantly larger than in the corresponding control plots after rewetting,
419 indicating positive legacy effects and a high resilience of the investigated grasses (Figs. 4 and 8). Interestingly, we did
420 not only observe growth rates that were larger in the treatment plots than in the control plots immediately after the drought
421 release, but observed larger growth rates in all treatment plots compared to the control plots even in the first harvests of
422 the following growing season (Fig. 4). This pattern was consistent for both years of the experiment. Bloor and Bardgett
423 (2012) and also Denton et al. (2017) found that drought events promote soil fertility and nutrient retention following
424 drought release. Likewise, Gordon et al. (2008) found an increase in microbial activity after a rewetting event, possibly
425 leading to a rapid and sudden influx of plant available nitrogen in the soil (Mackie et al., 2018; Schimel and Bennett,
426 2004). Hofer et al. (2017a) also attributed growth increases relative to control plots in post-drought periods to nitrogen
427 availability in the soil and Karlowsky et al. (2018) found evidence that interactions between plants and microbes increase
428 plant nitrogen uptake in grasslands after rewetting events. It could, thus, be that the enhanced productivity in the treatment
429 plots following drought release is the result of increased microbial activity leading to enhanced nitrogen availability
430 and/or changes in resource limitation following drought release as suggested by Seastedt and Knapp (1993) in their
431 Transient Maxima Hypothesis.

432 We applied nitrogen fertilizer in our experiment to each plot after each harvest, also at the beginning and in the
433 middle of a drought treatment. Since we applied the fertilizer in form of water-soluble pellets, it is possible that nitrogen
434 fertilizer pellets accumulated in the drought-treated plots during the treatment phase. The rewetting of the soil could have

435 resulted in a massive release of nitrogen fertilizer from these pellets so that plant growth rates in formerly drought-stressed
436 plots were stimulated by the release of this fertilizer and, thus, larger than those of the control plots. However, Hofer et
437 al. (2017a) observed strongly increased N availability and plant growth rates after drought release not only in plots that
438 received mineral fertilizer during the drought treatment period, but also in plots that did not receive any N fertilizer during
439 drought. We suggest therefore that the release of accumulated fertilizer nitrogen in the treatment plots might explain
440 some, but not all post-treatment growth responses in the formerly drought treated plots in our study.

441 Hagedorn et al. (2016) have shown that rewetting events trigger intrinsic processes that lead to a sudden increase
442 of photosynthesis in young beech trees. Moreover, Arend et al. (2016) found a rapid stimulation of photosynthesis
443 immediately after rewetting that continued until the end of the growing season, partly compensating the loss of
444 photosynthetic activity during drought. Hofer et al. (2017b) found an increased root mass and increased water-soluble
445 carbohydrate reserves in the stubbles of drought stressed *L. perenne* at the end of a drought stress period. Both of which
446 could have contribute to increased growth rates observed in their study once rewetting had occurred. Also, drought-
447 induced shifts in plant phenology could lead to a shift in high productive stages, e.g. leading to peak growth rates not in
448 spring, but in summer (O'Toole and Cruz, 1980). With the data we collected throughout our experiment, we cannot clearly
449 identify the mechanisms behind the strong post-drought growth increase that extended even into the next growing season.
450 In the end, several biogeochemical and ecophysiological mechanisms might be responsible for the overcompensation of
451 growth following drought release.

452

453 **4.5 The grasses only slightly differed in drought resistance and resilience**

454 During the seasonal drought events the six tested grasses showed a mostly universal response with only slight and not
455 consistent differences in their growth rate reductions. Post-drought legacy effects differed among the different grasses in
456 the second year (grass x treatment; p =n.s. for 2014 and p <0.001 for 2015). *D. glomerata* and *P. pratensis* showed a high
457 potential for resilience and overcompensation after drought, while *L. multiflorum* generally showed the lowest resilience.
458 Wang et al. (2007) found that plant communities consisting of less productive species were more resistant to drought than
459 plant communities consisting of more productive species. The fact that inter-specific differences in the responses to the
460 drought stress and to the following rewetted post-drought period in our study were smaller than in other studies, may be
461 related to the fact that all six tested grasses belong to a relatively narrow functional group of productive fast-growing
462 grasses with high demands for mineral N in the soil. The availability of mineral N in the soil was found to be a key factor
463 for the response during as well as after drought for non-leguminous species (Hofer et al., 2017a, 2017b).

464

465 **4.6 Small to moderate impact of seasonal drought on annual aboveground net primary production**

466 Although the immediate effects of drought on growth rates were severe in all three seasons in our study, the overall effects
467 on total annual ANPP of 4 to 14% were only small to moderate compared to drought effects observed in other studies
468 (Gherardi and Sala, 2019; Wilcox et al., 2017; Wu et al., 2011) (Fig. 9a). We also did not find any consistent effects of
469 the drought timing on annual NPP, contrary to other studies (Denton et al., 2017; La Pierre et al., 2011; Nippert et al.,
470 2006; Petrie et al., 2018). This is likely a consequence of the small overall drought effects on annual ANPP in our study.
471 The small drought effects on annual ANPP that we report here can be explained by the high resilience of growth rates in
472 the treatment plots following the drought release. This is in particular evident in the spring treatment, where we observed
473 on the one side the largest absolute reduction in growth in response to drought, but at the same time also the strongest
474 positive legacy effects after drought, leading to relatively small total drought effects on annual aboveground ANPP.
475 Because the fall drought treatment period lasted until the end of the vegetation period, the positive post-drought legacy
476 effects for this treatment were not included in the calculation of annual biomass production. Nevertheless, the fall drought
477 treatment in 2014 did also not strongly affect the annual aboveground ANPP. This is because the growth period affected
478 by the fall drought treatment, was the least productive part of the growing season, and, thus contributed only little to the
479 annual productivity.

480 The overall effect of drought on annual ANPP might also be small compared to other studies because our study
481 was conducted in highly productive grasslands that according to best practice management were harvested six times in
482 the growing season. The drought treatments occurred, however, only in two out of these six growth periods throughout
483 the growing season. In addition, the first sheltered growth period generally did not show a reduced growth rate (Fig. 4),
484 because the soil with its water holding capacity acted as a buffer. With the absence of negative legacy effects, the impact
485 of the immediate drought effect of one drought stressed growth period on annual NPP was therefore diluted by the five
486 other harvests of the vegetation period (Finn et al., 2018).

487 The majority of studies that have assessed the impact of drought on grassland productivity have either assessed
488 immediate drought effects, i.e. drought resistance (Bollig and Feller, 2014; Kahmen et al., 2005; Walter et al., 2012;
489 Wang et al., 2007), or have assessed the net effects of drought on annual NPP (Gherardi and Sala, 2019; Wilcox et al.,
490 2017; Wu et al., 2011). Our study highlights that it is important to also quantify immediate and post-drought effects –
491 even in the following growing season – if the causes of drought reduced annual productivity are to be understood.

492 Effects of drought on annual aboveground NPP of grasslands have been shown to vary, depending on the severity
493 of the experienced drought (Vicca et al., 2012; Wilcox et al., 2017), ecosystem type (Byrne et al., 2013; Gherardi and
494 Sala, 2019; Sala et al., 2015; Wilcox et al., 2017), the intensity of land use (Vogel et al., 2012; Walter et al., 2012), the
495 plant functional composition (Gherardi and Sala, 2015; Hofer et al., 2016, 2017a; Mackie et al., 2018), or the biodiversity
496 of an ecosystem (Isbell et al., 2015; Kahmen et al., 2005; Wagg et al., 2017). In accordance with work in C4 grasslands,
497 our study shows that the timing of a drought event in the growing season is crucial for the immediate effects of a drought

498 on grassland productivity. Importantly, however, our study also shows that strong positive legacy effects can occur after
499 rewetting and that these legacy effects are even important in spring of the next year. These effects can partially compensate
500 the strong immediate drought effects and lead relatively small overall seasonal drought effects on annual ANPP.

501 Author contributions:
502 AK and AL planned and designed the research. CH and SEH performed the experiments. CH analysed the data and wrote
503 the manuscript. AK and AL co-wrote the manuscript.

709 Tables

710 Table 1: Amount of rainfall fallen in the experiment and associated amount of excluded rainfall during the sheltered
 711 drought periods in the years 2014 and 2015. Growing season precipitation refers to the period of time between the set-up
 712 of the shelters and the last harvest of each year.

2014				
annual precipitation	growing season precipitation	spring	summer	fall
937.1	717.9	excluded precipitation (mm)		
		167.4	308.8	241.7
		excluded precipitation annually (%)		
		17.9	33.0	25.8
excluded precipitation in growing season (%)				
		23.2	43.0	33.7
2015				
annual precipitation	growing season precipitation	spring	summer	fall
801.9	648.5	excluded precipitation (mm)		
		296.9	204.7	149.9
		excluded precipitation annually (%)		
		37.0	25.5	18.7
excluded precipitation in growing season (%)				
		45.8	31.6	23.1

713

714 Table 2: (a) Median of soil water potential and (b) average air temperature during the two growth periods of the drought
 715 treatments and the two post-drought growth periods as well as the corresponding periods of the rain-fed control. n.a.: not
 716 available.

a)	Growth period	Control			Treatment		
		spring	summer	fall	spring	summer	fall
	2014	MPa					
	1 st drought	-0.03	-0.41	-0.01	-0.09	-0.72	-0.73
	2 nd drought	-0.01	-0.01	-0.01	-1.44	-1.44	-1.61
	1 st post-drought	-0.41	-0.01	-0.01	-1.1	-0.05	-0.01
	2 nd post-drought	-0.01	-0.01	n.a.	-0.01	-0.02	n.a.
	2015	MPa					
	1 st drought	-0.01	-0.02	-0.14	-0.08	-0.45	-0.85
	2 nd drought	-0.01	-0.25	-0.34	-0.77	-0.83	-1.34

717

718 Table 3: Summary of analysis for the effects of season, drought treatment, grass, and their interactions on temperature-
 719 weighted growth rates (DMYTsum, natural log-transformed) from the second growth period during drought (weeks six
 720 to ten). The inference (F - and p -values) and the R^2 refer to the fixed effects from the linear mixed model. df_{num} : degrees
 721 of freedom term, df_{den} : degrees of freedom of error.

Effect	df_{num}	df_{den}	2014		2015	
			F -value	p	F -value	p
Season (spring, summer, fall)	2	36	1051.1	<0.001	2655.3	<0.001
Treatment (control vs. drought)	1	72	341.9	<0.001	642.9	<0.001
Grass	5	72	9.4	<0.001	14.2	<0.001
Season \times Treatment	2	72	25.9	<0.001	366.2	<0.001
Season \times Grass	10	36	6.8	<0.001	10.3	<0.001
Treatment \times Grass	5	72	2.9	0.018	2.0	0.094
Season \times Treatment \times Grass	10	72	3.3	0.001	3.4	0.001
R^2			0.901		0.965	

722

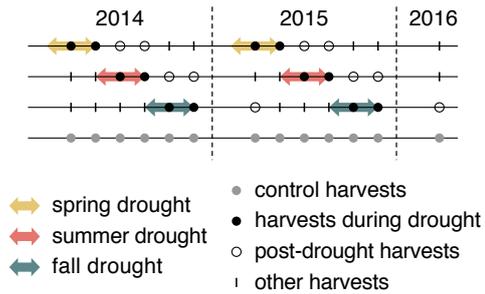

723 Table 4: Summary of analysis for the effects of season, drought treatment, grass, and their interactions on temperature-
 724 weighted growth rates (DMYTsum, natural log-transformed) from the second post-drought growth period (weeks six to
 725 ten). See Table 3 for additional explanation.

Effect	df _{num}	df _{den}	2014		2015	
			<i>F</i> -value	<i>p</i>	<i>F</i> -value	<i>p</i>
Season (spring, summer, fall)	2	36	783.4	<0.001	1428.6	<0.001

727 Figures

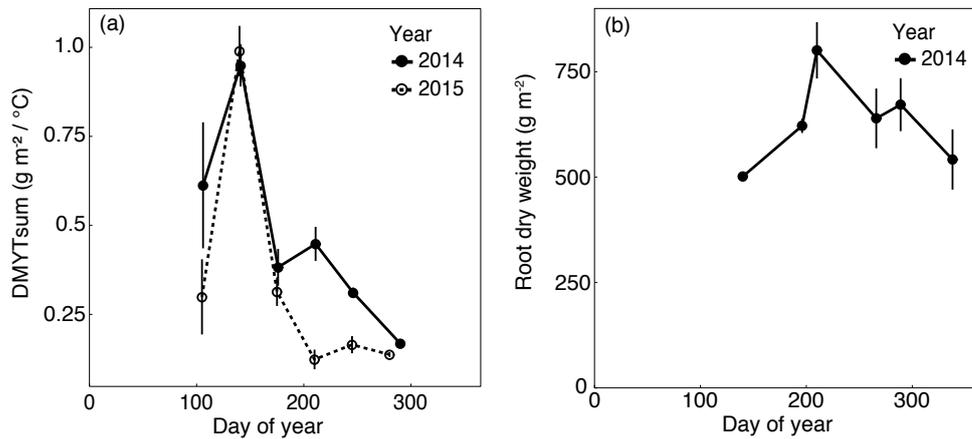

728

729 Fig. 1: Experimental design; experiment lasted two consecutive years (2014, 2015) with six evenly distributed harvests
730 in both years and one additional harvest in the beginning of 2016. Arrows indicate the duration of each drought treatment
731 (ten weeks). Each treatment was replicated four times with each of six grasses.

733 Fig. 2: (a, f) Daily evapotranspiration (ET) and vapor pressure deficit (VPD), (b-e, g-k) daily rainfall and soil water
734 potential (Ψ_{soil}) in 10 cm depth over the growing seasons 2014 (a-e) and 2015 (f-k) for the control and drought treatment
735 (sensors per treatment: $n=8$). Grey shaded areas represent the experimental drought when rainfall was excluded. Dashed
736 horizontal line shows permanent wilting point ($\Psi_{\text{soil}}=-1.5\text{MPa}$). Dashed vertical lines represent dates of harvest. Arrows
737 indicate watering events (in control plots only).

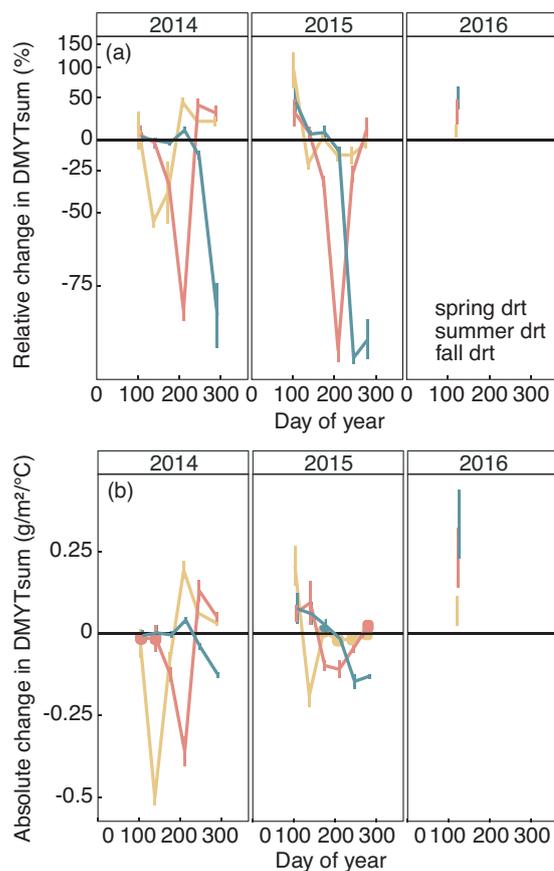

738

739 Fig. 3: (a) Temperature-weighted growth rates (DMYTsum) of aboveground biomass of rain-fed control plots in 2014

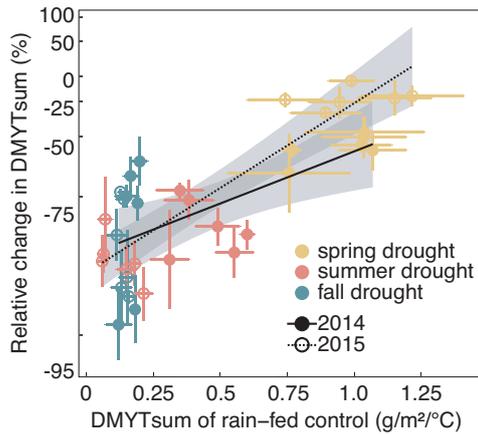

740 and 2015; values are means across all six investigated grasses and four replicates (n=6, ± se) and b) belowground biomass

741 of rain-fed control plots in 2014; values are means across the four grasses *L. perenne* early (LPe) and late (LPI) flowering

742 and *D. glomerata* early (DGe) and late (DGI) flowering (n=4, ± se).

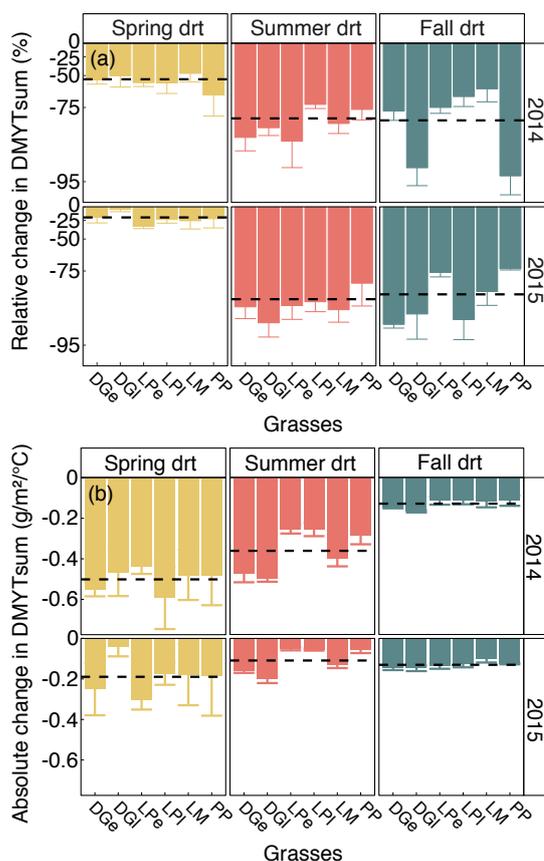

743 Fig. 4: (a) Relative (RCG) and (b) absolute (ACG) changes in temperature-weighted growth rates (DMYTsum) of the
744 respective drought (drt) treatment compared to the control (ctr) for 2014, 2015 and 2016. Values are means \pm se across
745 all six investigated grasses each in four replicates. Values below the horizontal black line indicate reduced growth
746 compared to the control. Values above the line indicate an increase of growth.
747 $RCG=100 \times (DMYTsum(drt)/DMYTsum(ctr))-1$; displayed on log-scale); $ACG=DMYTsum(drt)-DMYTsum(ctr)$.

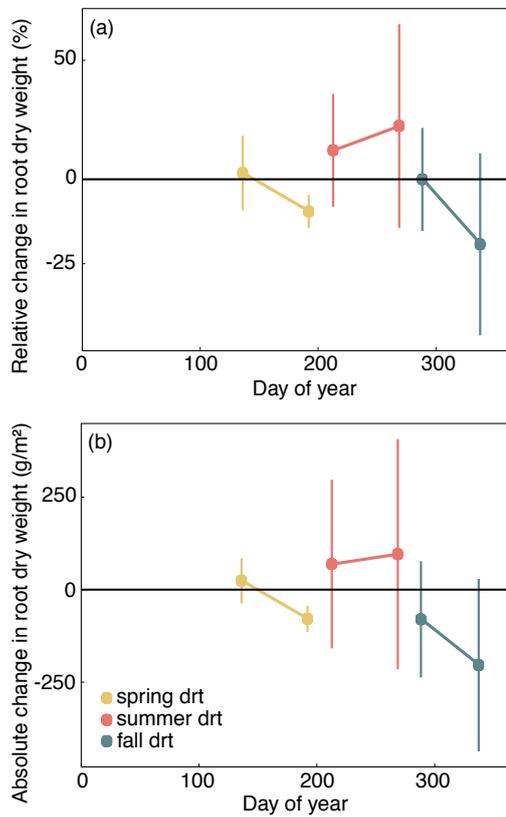

748

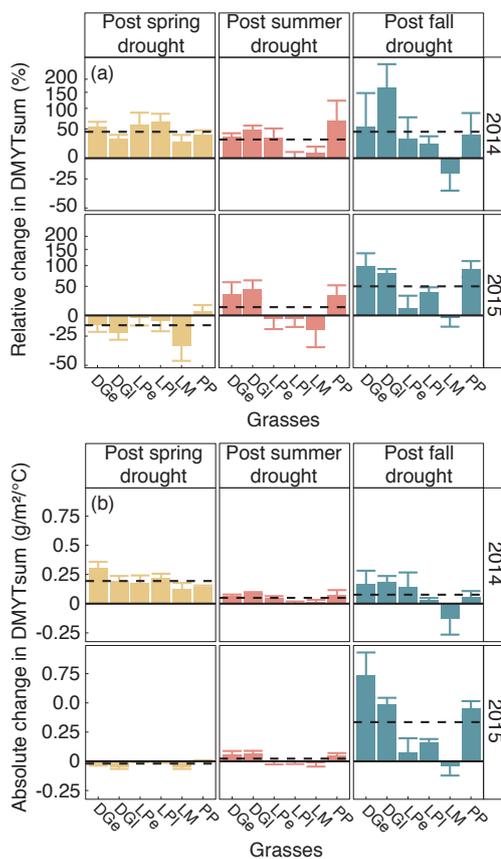

749 Fig. 5: Relative changes of temperature-weighted growth rate due to drought (RCG; %) as a function of temperature-
750 weighted growth rate (DMYTsum) of the corresponding rain-fed control plots ($\text{g}/\text{m}^2/^\circ\text{C}$). Values are means \pm se for all
751 six investigated grasses each in four replicates.

752 Fig. 6: (a) Relative (RCG) and (b) absolute (ACG) changes in temperature-weighted growth rates (DMYTsum) for the
 753 second growth period (weeks six to ten) of the respective drought (drt) treatment for 2014 and 2015 for the individual
 754 grasses. Values are means of four replicates \pm se. Dashed black lines represent the means across all grasses. See Fig. 4
 755 for additional explanation.

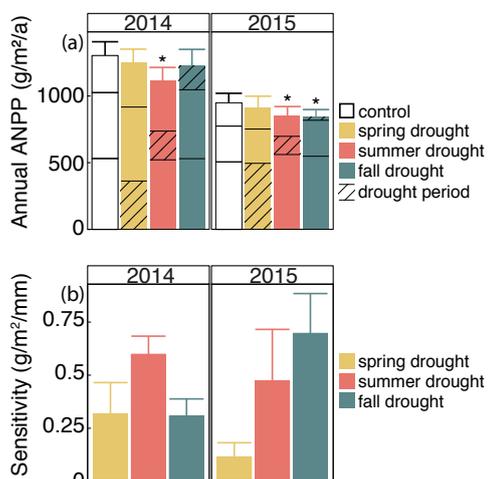

756 Fig. 7: (a) Relative and (b) absolute changes in root dry matter at the end of each drought treatment and after six to eight
757 weeks after drought-release in 2014. Values are means \pm se of four grasses of *L. perenne* (LPe and LPl) and *D. glomerata*
758 (DGe and DGl) each in four replicates.

759

760 Fig. 8: (a) Relative (RCG) and (b) absolute (ACG) changes in temperature-weighted growth rates (DMYTsum) for the
 761 second post-drought growth period (weeks six to ten) in 2014 and 2015 after the respective drought (drt) treatment for
 762 the individual grasses. Values are means of four replicates \pm se. Post-drought growth period of the fall drought treatment
 763 is the first growth period of the following year. See Fig. 4 for additional explanation.

764

765 Fig. 9: (a) Annual ANPP under rain-fed control and under the three seasonal drought treatments and (b) sensitivity of the
766 three seasonal drought treatments in the years 2014 and 2015. Values are means \pm se across all six investigated grasses
767 each in four replicates. Bars in (a) are stacked according to growth in spring (bottom part), summer and fall (top part).
768 Significant differences to the control are marked with * ($p < 0.05$).
