**Abstract.** Coccolithophores are globally important marine calcifying phytoplankton that utilize a haplo-diplontic life cycle. The haplo-diplontic life cycle allows coccolithophores to divide in both life cycle phases, and has been proposed to allow coccolithophores to expand their niche space. To-date research has however largely overlooked the life cycle of coccolithophores, and has instead focused on the diploid life cycle phase. Through a synthesis of global scanning electron microscopy (SEM) coccolithophore abundance data ( $n = 2534$ ), we show that the haploid life cycle phase contributes significantly to coccolithophore abundance, constituting  $\approx 18\%$  of species abundance for which haploid-diploid pairs are defined. Using hypervolumes to quantify the niche space of coccolithophores, we furthermore show that the haploid and diploid life cycle phases inhabit contrasting niches, and that this allows coccolithophores to expand their niche space by  $\approx 17\%$ . Our results highlight that future coccolithophore research should consider both life cycle stages, as omission of the haploid life cycle phase in current research limits our understanding of coccolithophore ecology.

## 1 Introduction

Coccolithophores are marine phytoplankton that produce calcium carbonate platelets, called ‘coccoliths’, which can be seen from space when coccolithophores bloom. Coccoliths eventually rain down into the ocean interior or serve as ballasts as they are incorporated into faecal pellets and aggregates, which drives the carbonate pump and increases organic carbon export rates to the deep sea (Klaas and Archer, 2002). Through the production of coccoliths, coccolithophores produce  $\approx 1.5$  Pg of inorganic carbon per year (Hopkins and Balch, 2018; Krumhardt et al., 2019), and subsequently account for 30 % to 90 % of carbonate in sediments (Broecker and Clark, 2009).

In addition to the carbonate pump, coccolithophores contribute to the organic carbon pump, accounting for 1-40 % of marine primary production depending on habitat (Poulton et al., 2007, 2013). Because of involvement in the ocean carbon pumps and food web, coccolithophores thus play an important role in the ocean on regional to global spatial scales and seasonal to geological time scales.

Much focus has been put on understanding coccolithophore ecology and physiology, such as the function of calcification (Young, 1994; Monteiro et al., 2016; Xu et al., 2016), their diversity (Aubry, 2009; Young et al., 2003), the factors controlling their calcification (Zondervan, 2007; Taylor et al., 2017) and competitiveness (Margalef, 1978; Krumhardt et al., 2017). However, one factor that significantly impacts coccolithophore calcite production and potentially their global success, has been given little attention: their distinctive life cycle.

The life cycle of an organism is defined by the number of chromosome sets (the 'ploidy level') of the cell when asexual reproduction ('mitosis') occurs. If mitosis occurs when the cell has one set of chromosomes (a haploid cell) the life cycle is called 'haplontic' (Fig. 1a), while if mitosis occurs when the cell has two sets of chromosomes (a diploid cell) the life cycle is called 'diplontic' (Fig. 1b). A few organism can divide in both the haploid and diploid phase. Such a life cycle is called 'haplo-diplontic' (Fig. 1c). Coccolithophores utilize the latter life cycle strategy - which is in contrast to dinoflagellates and diatoms which tend to be either haplontic or diplontic, and as such can only divide in either the haploid or diploid life cycle phase (Von Dassow and Montresor, 2011).

The haploid and diploid life cycle phases of coccolithophores can vary significantly in terms of coccolith structure, size and morphology, cell size, and degree of calcification (Fig. 2). The diploid life cycle phases tend to be more heavily calcified than the haploid life cycle phases, which tend to be more lightly, or non-calcified (Cros et al., 2000; Daniels et al., 2016; Fiorini et al., 2011a, b). This difference in cell calcium carbonate content, cell organic carbon content, and ratio thereof (the PIC:POC ratio), between the two life cycle phases means that the two phases potentially have contrasting impacts on the carbonate pump.

Although coccolithophore morphology is highly diverse, the diploid phases of coccolithophores primarily utilize hetero-coccolithophore morphology (with some exceptions, i.e. *Braarudosphaera bigelowii*), while the haploid life cycle phases can broadly be classified into four morphologies: polycrater (Fig. 2a), ceratolith (Fig. 2b), holococcolith (Fig. 2c-i) and unmineralized (not pictured) (Frada et al., 2018). Of these four haploid morphologies, the holococcolithophore morphology - which is defined by rhomboid calcite structures that constitute the coccoliths - is the most frequent utilized (Frada et al., 2018). Eight coccolithophore clades utilize holococcoliths, while four clades utilize an unmineralized haploid morphology, one clade utilizes a ceratolith morphology, one clade utilizes ceratolith morphology, and for five clades the haploid morphology is currently unknown (Frada et al., 2018).

Coccolith and coccosphere morphology, cell and coccosphere size, and the degree of calcification influences coccolithophore ecology (Young, 1994). We can thus expect that the haploid and diploid life cycle phases of coccolithophores can have contrasting ecological preferences, which has been proposed to allow a coccolithophore species to occupy multiple niches (Houdan et al., 2006; Frada et al., 2012; Cros and Estrada, 2013; Godrijan et al., 2018; Frada et al., 2018). This ability to occupy multiple niches should expand the total niche space coccolithophore can inhabit, a potential advantage for haplo-diplontic organisms in

variable environments (Mable and Otto, 1998). An idea which is supported by genetic models (Hughes and Otto, 1999; Rescan et al., 2015).

While niche differentiation has been widely observed for haplo-diplontic seaweeds (Couceiro et al., 2015; Guillemin et al., 2013; Lees et al., 2018; Lubchenco and Cubit, 1980), and coccolithophores (Houdan et al., 2006; Cros and Estrada, 2013; Godrijan et al., 2018; Frada et al., 2018), to-date no research has quantitatively investigated the extent of niche overlap and niche expansion for haplo-diplontic algae. For coccolithophores this is because research has primarily focused on the diploid life phases, and relatively little is known in regards to the haploid life phase (Taylor et al., 2017; Frada et al., 2018). This is in part due to a research focus on the globally ubiquitous *Emiliania huxleyi* which utilizes an unmineralized haploid morphology which cannot be readily identified with conventional light or scanning electron microscopy (Frada et al., 2008).

With the aim of understanding how haploid coccolithophores contribute to coccolithophore success, we quantify the niche overlap and niche expansion between haploid and diploid life stages of coccolithophores for the first time.

To do so, we compile global coccolithophore abundance observations of coccolithophores using all available SEM measurements and where appropriate corresponding environmental measurements (temperature, salinity, fixed nitrogen, phosphate, and silicate). Although our focus is on holococcolith forming clades rather than *E. huxleyi*, holococcolith forming clades include ecologically relevant species such as *Helicosphaera carteri* (Fig. 2e), *Coccolithus pelagicus* and *Calcidiscus leptoporus* (Fig. 2i) which contribute more to the  $\text{CaCO}_3$  flux to the deep ocean than *E. huxleyi* due to their larger coccolith and coccosphere size (Ziveri et al., 2007; Rigual Hernández et al., 2019).

In addition to niche overlap and niche expansion, we investigate the dataset to identify ecological preferences of holococcolith forming species, providing an updated picture on their global distribution, relative abundance, niche space, and environmental controls. This work provides key information to better understand how the haplo-diplontic life cycle contributes to coccolithophore success.

## 2 Methods

### 2.1 Metadata compilation

Coccolithophore abundance measurements were compiled from 36 studies, constituting 2534 measurements, and representing all major oceans (Table 1). These studies utilized scanning electron microscopy (SEM) to enumerate or further identify coccolithophores rather than solely relying on the more commonly utilized light or cross polarized microscopy which under-represents coccolithophore biodiversity (Godrijan et al., 2018), in particular holococcolithophores (Bollmann et al., 2002; Cerino et al., 2017). We used this data set to investigate global, and vertical distribution patterns of haploid and diploid coccolithophore life cycle phases, specifically focusing on holococcolith forming species.

In addition to the global data set, we further investigated three case studies, in order to better understand specific drivers and differences between the life cycle phases: the Atlantic Meridional Transect (AMT), representative of mid-oligotrophic open ocean ecosystems, the long term time series at Bermuda (BATS), and two time series in a mesotrophic coastal ecosystem in the Adriatic Sea (the 'Mediterranean data set'). For the AMT study, we considered observations from 4 cruises, specifically AMT-

85 12 (May-Jun 2003), AMT-14 (Apr-Jun 2004), AMT-15 (Sep-Oct 2004) and AMT-17 (Oct-Nov 2005) previously published by Poulton et al. (2017). For the BATS station we considered data published by Haidar and Thierstein (2001), which consists of approximately monthly observations between January 1991 to January 1994. For the Mediterranean study, we combine two time-series in the Adriatic Sea by Godrijan et al. (2018) and Cerino et al. (2017), between September 2008 to December 2009 and May 2011 to February 2013 at the RV-001 and C1-LTER stations respectively.

90 For the AMT and Mediterranean case studies, we additionally compiled temperature, salinity, and concentrations of fixed nitrogen (nitrite + nitrate), phosphate, and silicate. For the AMT environmental variables were acquired from the British Oceanographic Data Centre (BODC). For the Mediterranean study, day length was calculated using the MIT Skyfield package in Python.

All data was acquired from supplementary data, online databases, or if neither was available by contacting the authors directly. The data was manually checked for synonyms or misspellings of species names, and where appropriate cell abundances were converted to cells  $l^{-1}$ . All species, or genera if not identified to a species level, were labeled as either heterococcolithophore, holococcolithophore, or 'other', which includes polycrater, nanoliths, and unidentified species. For these categorizations we followed definitions from Cros and Fortuño (2002).

100 The species and environmental data were compiled in Python, and subsequently analysed in R (R Core Team, 2019). For all analysis we only considered samples within the top 200 m of the water column. On a global scale and regional scale, we calculated the mean and highest observed abundances (the 'maximum abundance') of both hetero- and holococcolithophores. For the mean abundance calculations the mean was calculated for each sample and then averaged.

## 2.2 Definition of pairs and HOLP-index

Not all heterococcolithophore forming coccolithophore species form holococcospheres. Thus, to better illustrate the proportion of haploid and diploid coccolithophore cells, we reported the ratio between hetero- and holococcospheres of species that form holococcoliths in their haploid phase, which is commonly implemented (Cros and Estrada, 2013; Šupraha et al., 2016).

This ratio is referred to as the 'HOLP-index', and is defined by Cros and Estrada (2013) as:

$$\text{HOLP-index} = 100 \cdot \frac{\text{paired holococcolithophore abundance}}{\text{paired coccolithophore abundance}} \quad (1)$$

110 Species included in the HOLP-index follow the definitions of paired species as defined in Frada et al. (2018) (Table 2) - which is confined to currently understood associations and which is likely to change as our understanding holococcolith species continues to improve. We calculated the HOLP-index on a global and regional level for studies that identified holococcolithophores to a species level, the AMT data set, and the Mediterranean data set. To calculate the mean HOLP-index, the ratios were calculated for each sample and then averaged.

## 2.3 Environmental drivers

115 We quantified the environmental drivers of hetero- and holococcolithophore abundance and the HOLP-index for the AMT and Mediterranean data sets using Spearman correlations. We calculated Spearman correlations for hetero- and holococcol-

ithophores and the HOLF-index relative to temperature, salinity, depth, and concentrations of fixed nitrogen (nitrite + nitrate), phosphate, and silicate for the AMT data set. The same ordinal associations were calculated for the Mediterranean data set, but we considered day length instead of depth, because only the top 30 meters of the water column was sampled, and seasonality is an important driver in this region. To focus on marine systems of coccolithophores, we only considered samples with salinities above 30 ppt. Samples missing any environmental variables were removed. Subsequently the AMT data set included a total of 45 samples, and the Mediterranean data set 100 samples. Spearman correlation was performed in R using the 'cor.test' function from the 'stats' package (R Core Team, 2019). We also visualised environmental drivers by plotting the distributions of cell concentrations and environmental parameters within the water column or within the first two axes of a Principal Component Analysis (PCA), and then interpolating values using the Multilevel B-spline Approximation (MBA) algorithm described by Lee et al. (1997). Prior to conducting the PCA, samples with a Cook's Distance greater than 4 times the sample size were removed. For the visualizations, we used the same environmental parameters and samples as for the Spearman correlations, except for the AMT data set where we plotted chlorophyll instead of depth - which allowed visualization of the deep chlorophyll maximum (DCM). For the AMT data set, we plotted the abundance and environmental parameters as a function of latitude and depth. While for the Mediterranean data set the variables were plotted as a function of the first two axes of a PCA which included temperature, salinity, day length, and concentrations of phosphate, fixed nitrogen, and silicate. The MBA interpolation was performed with the 'mba.surf' function from the 'MBA' R package (Finley et al., 2017), and the PCA was performed with the 'dudi' function of the 'ade4' package (Dray and Dufour, 2007). Cook's distances were calculated using the 'lm' and 'cooks.distance' functions provided in the 'stats' R package (R Core Team, 2019).

## 135 2.4 Seasonality

To investigate seasonality we compared monthly hetero- and holococcolithophore abundance data to temporal variations of temperature, salinity, day length, and concentrations of phosphate, fixed nitrogen, and silicate of the BATS and Mediterranean data sets.

## 2.5 Niche overlap and niche expansion

140 Distribution patterns of phytoplankton are influenced by multiple environmental drivers. These environmental drivers form a n-dimensional hyperspace within which hypervolumes can be defined based on where the phytoplankton occur. This hypervolume can be used to quantify niche space (Hutchinson, 1957) and allows comparisons between multiple phytoplankton - in this instance the two life cycle phases of coccolithophores.

145 Although processing hypervolumes is challenging due to their high dimensionality, methods described by Blonder et al. (2014) allow hypervolume quantification and comparison (for further discussion see Blonder (2018) and Mammola (2019)). Using this strategy we determine the niche overlap of hetero- and holococcolithophores in hyperspace using the Sørensen-Dice and Jaccard similarity metrics.

We furthermore calculate the ‘niche expansion’ of the haplo-diplontic life cycle strategy, which we define here as the non-overlapping region of either phase within hyperspace. In other words:

$$150 \quad NE(A) = \frac{|A| - |A \cap B|}{|A \cup B|} \quad (2)$$

Where  $NE(A)$  = niche expansion of A; A = hypervolume A; B = hypervolume B;  $\cap$  = intersection between two hypervolumes;  $\cup$  = union between two hypervolumes

We calculated the Jaccard and Sørensen-Dice similarity metrics and niche expansion for both the Atlantic Ocean and Mediterranean Sea data set. For the Atlantic Ocean, nitrogen showed high Pearson correlation to silicate ( $\rho = 0.95$ ,  $p < 0.001$ ) and phosphate ( $\rho = 0.90$ ,  $p < 0.001$ ). We thus only considered temperature, salinity and the concentration of fixed nitrogen in this region. Although no such correlations were observed for the Mediterranean data set, to make the niche metrics comparable in both regions, the silicate and phosphate concentration of the Mediterranean data set were also excluded. The environmental data were normalized using z-scores prior to analysis. Niche overlap and niche expansion was calculated only for species for which both life cycle phases were observed.

160 We used the ‘hypervolume’ R package (Blonder and David J. Harris, 2018) to conduct our niche overlap and niche expansion analysis. Gaussian kernel density estimation (R function ‘hypervolume\_gaussian’) was used to construct the hypervolume, the overlap metrics were calculated with the ‘hypervolume\_overlap\_statistics’ R function, and the volume and intersection of hypervolumes were calculated using the ‘get\_volume’ R function.

### 3 Results

#### 165 3.1 Biogeography of coccolithophores

Within our compilation heterococcolithophores showed global distribution, while holococcolithophores were noticeably absent at the ALOHA station in Hawaii and (with some exceptions)  $>50^\circ$  S in the Southern Ocean (Fig. 3 and Table 3).

Highest maximum abundances of heterococcolithophores were observed at high latitudes within the Arctic circle ( $>66^\circ$  N) ( $\approx 4.37 \times 10^6$  cells  $l^{-1}$ ), and the Southern Ocean ( $>40^\circ$  S and  $<65^\circ$  S) ( $\approx 1.64 \times 10^6$  cells  $l^{-1}$ ). Low maximum abundances were observed in most of the subtropical and tropical waters such as the Arabian Sea ( $\approx 1.11 \times 10^5$  cells  $l^{-1}$ ), East China Sea ( $\approx 2.39 \times 10^5$  cells  $l^{-1}$ ), and East Indian Ocean ( $\approx 2.27 \times 10^5$  cells  $l^{-1}$ ).

The regions with the highest mean heterococcolithophore abundance differed from the regions where highest maximum heterococcolithophore abundance were observed. For example, the highest mean abundance was observed in the East Indian Ocean ( $\approx 1.96 \times 10^5$  cells  $l^{-1}$ ); which was higher than the mean abundance in the Southern Ocean ( $\approx 8.87 \times 10^4$  cells  $l^{-1}$ ), North Atlantic ( $\approx 9.99 \times 10^4$  cells  $l^{-1}$ ) and Arctic Circle ( $\approx 5.71 \times 10^4$  cells  $l^{-1}$ ).

175 Although holococcolithophores showed low abundances at high latitude regions in the Southern Hemisphere, highest maximum holococcolithophore abundances were observed in the Arctic circle ( $>66^\circ$  N) ( $\approx 2.23 \times 10^5$  cells  $l^{-1}$ ). High maximum abundances were additionally observed in the Mediterranean Sea ( $\approx 1.38 \times 10^5$  cells  $l^{-1}$ ). Generally low maximum abundances

were observed at tropical and subtropical basins such as the Arabian Sea ( $\approx 5.63 \times 10^3$  cells  $l^{-1}$ ); with exception of the East  
180 Indian Ocean ( $\approx 3.10 \times 10^4$  cells  $l^{-1}$ ). Medium maximum abundances were observed in the North Atlantic Ocean ( $\approx 3.00 \times 10^4$  cells  $l^{-1}$ ). On average the Mediterranean Sea had the highest mean holococcolithophore abundance ( $\approx 6.00 \times 10^3$  cells  $l^{-1}$ ), followed by the East Indian Ocean ( $\approx 4.40 \times 10^3$  cells  $l^{-1}$ ), and the Arctic Circle ( $\approx 1.70 \times 10^3$  cells  $l^{-1}$ ). The lowest mean abundances were observed in the Southern Ocean ( $\approx 4.00$  cells  $\times 10^2$   $l^{-1}$ ), and Arabian Sea ( $\approx 4.60 \times 10^2$  cells  $l^{-1}$ ).

Overall holococcolithophores contributed 7.3 % ( $\pm 16$  %) to total coccolithophore abundance globally, with their highest  
185 contribution observed in the Mediterranean Sea (16.5 %  $\pm 22.7$  %) (Table 3). However, on a regional basis (Table 4) holococcolithophores generally contributed less than 6 % to total coccolithophore abundances. The contribution of holococcolithophores to paired species was much higher than when all hetero- and holococcolithophores are considered (Table 4), with a HOLP-index of 18.3 % ( $\pm 28.2$  %) globally, and the highest HOLP indices observed off the coast of Chile in the South Pacific (36.2 %  $\pm 37.4$  %), the Central Atlantic (30.2 %  $\pm 25.2$  %), and the Mediterranean Sea (27.7 %  $\pm 30.1$  %). The average  
190 HOLP-index was above 15.7 % for all locations, except in the Southern Ocean where an HOLP-index of 7.1 % ( $\pm 23.7$  %) was observed.

### 3.2 Vertical distribution

In the global data set heterococcolithophore abundance is evenly distributed with depth, while holococcolithophore abundance is highest in the top 50 m of the water column (Fig. 4).

195 For holococcolithophores the vertical distribution pattern is mainly driven by paired holococcolithophore species which constituted  $\approx 62.2$  % to total coccolithophore abundance. Two currently unpaired holococcolithophores also contribute to the depth distribution trend with *Helladosphaera cornifera* (for which the association has to be further confirmed) constituting  $\approx 8.1$  % of total holococcolithophore abundance, and *Corisphaera gracilis* (for which no pair has been described) constituting  $\approx 3.6$  % of total holococcolithophore abundance. Subsequently paired holococcolithophore abundances broadly followed the  
200 same patterns observed when all holococcolithophores were considered.

In comparison to holococcolithophores, depth distribution of heterococcolithophores was driven by unpaired species - in particular *E. huxleyi* which constituted  $\approx 59.2$  % of total heterococcolithophore abundance, but also by the presence of unpaired deep water species such as *Ophiaster formosus*, *Florisphaera profunda*, *Calciopappus caudatus*, and *Oolithotus antillarum*. However, although paired heterococcolithophores only contributed  $\approx 5.7$  % to total heterococcolithophore abundance, the depth  
205 distribution trends of paired and total heterococcolithophores species were similar.

### 3.3 Environmental drivers of niche partitioning

To further understand the distribution patterns observed on a global basis and within the water column we investigated the environmental drivers of hetero- and holococcolithophore abundance in the Atlantic Ocean (with the AMT data set) and the Mediterranean Sea. For the Atlantic Ocean data set, the environmental drivers were considered in the context of their distribution within the water column, whereas for the Mediterranean the environmental drivers were considered within PCA 'niche  
210 space'. These observed patterns were then further corroborated through Spearman analysis.

### 3.3.1 Atlantic Ocean

In the Atlantic Ocean both hetero- and holococcolithophores have highest abundances in the top 50 m of the water column (Fig. 5). However, a noticeable difference between hetero- and holococcolithophore distribution (Fig. 5a and Fig. 5d respectively) is the absence of holococcolithophores below the deep chlorophyll maximum (DCM) (Fig. 5l). The DCM tends to occur at 1-10 % irradiance levels, and is closely linked to the nutricline and thermocline (Poulton et al., 2006). The difference in depth distribution between hetero- and holococcolithophores, and the absence of holococcolithophores below the DCM may therefore be influenced by a combination of light limitation, high nutrient concentrations, and cold water temperatures at depth. This suggests that heterococcolithophores might be better adapted to exploit such conditions. Although differences in sinking rates - which are conceivably higher in the more heavily calcified heterococcolithophores could also factor into the difference in depth distribution between the two life cycle phases.

The distribution of heterococcolithophores (Fig. 5a) is primarily driven by *E. huxleyi* (Fig. 5c) which constitutes  $\approx 30$  % of total heterococcolithophore abundance in the data set. When only paired heterococcolithophore species were considered (Fig. 5b) a more even distribution in subtropical and tropical regions is observed. Holococcolithophores and paired holococcolithophores showed roughly similar distribution patterns (Fig. 5d and Fig. 5e).

Within the upper water column, heterococcolithophores showed highest abundance at higher latitudes ( $>35^\circ$  N and  $>30^\circ$  S), which is associated with a shallow mixed layer, lower salinity, and lower temperature, as well as increasing silicate concentrations in the southern hemisphere. Holococcolithophores meanwhile showed highest abundances at both high latitudes and in the Atlantic subtropical gyres. The HOLP-index (Fig. 5f) was highest within the Atlantic subtropical gyres, with a higher proportion of holococcolithophores in the Northern subtropical Gyre, which is associated with a shallower DCM relative to the Southern subtropical Gyre. This shallowing of the DCM on the AMT is however likely a seasonal signal as described by Poulton et al. (2006) and Poulton et al. (2017).

Spearman correlations (Table 6) suggests holococcolithophores are significantly ( $p < 0.05$ ) negatively correlated to phosphate, fixed nitrogen, silicate and depth and significantly positively correlated to temperature and salinity. Paired holococcolithophore and the HOLP-index showed the same correlation trends as holococcolithophores.

On the contrary, heterococcolithophores are only significantly and negatively correlated with depth and phosphate. While for paired heterococcolithophores significant negative correlations were observed with depth and silicate.

Thus hetero- and holococcolithophore abundance in the Atlantic Ocean seems primarily driven by the depth of the DCM both in terms of vertical and latitudinal distribution. Highest abundances of both hetero- and holococcolithophores are observed above the DCM, and heterococcolithophores are present below the DCM while holococcolithophores are not. In terms of latitude highest abundances of heterococcolithophores correspond to shallow DCM depth which occurs in higher latitude regions, and highest abundances of holococcolithophores occur in subtropical regions with deep DCM depths.

### 3.3.2 Mediterranean Sea

For the Mediterranean Sea long term time series, niche separation of hetero- and holococcolithophores within the PCA niche space (Fig 6), is primarily driven by Principal Component 1 (PC1) which is positively associated with temperature and day length and negatively associated with salinity, fixed nitrogen, silicate and phosphate (see Table 7). Heterococcolithophores are most abundant at low PC1 values (i.e. the left quadrants of Fig. 6a) which corresponds to low temperatures and short day lengths, and high salinity and concentrations of fixed nitrogen, silicate and phosphate. Holococcolithophores are most abundant at high PC1 values (i.e. the right quadrants of Fig. 6b), which corresponds to high temperatures and long day lengths, and low salinity and concentrations of fixed nitrogen, silicate and phosphate.

The pattern observed in the PCA niche space is also apparent in the Spearman correlations (Table 6) which indicate that heterococcolithophores are significantly negatively correlated to temperature, and day-length, and significantly positively correlated to phosphate, fixed nitrogen, silicate and salinity. For paired heterococcolithophore species the only significant correlation observed was a positive correlation with silicate.

Holococcolithophores showed an opposite pattern to heterococcolithophores, and are significantly positively correlated to day-length and temperature, and significantly negatively correlated to salinity, fixed nitrogen, silicate and phosphate. Paired holococcolithophores and the HOLP-index showed significant positive correlation to temperature and day length, but no significant correlations with the other environmental variables were observed.

### 3.3.3 General environmental trends

Our statistical analysis shows that in both the Mediterranean Sea and Atlantic Ocean holococcolithophores are generally found in low nutrient and warm environments and high light availability. However, an opposite trend was observed between the Atlantic Ocean and Mediterranean Sea in terms of correlation to salinity, with holococcolithophores positively correlated to salinity in the Atlantic Ocean and negatively correlated to salinity in the Mediterranean Sea. This difference in correlation to salinity may be explained by the different drivers of salinity in both regions. In the Atlantic Ocean, low salinity occurs at high latitudes, while high salinity corresponds to mid-ocean gyres due to higher evaporation in tropical and sub-tropical regions. In contrast, at the coastal site in the Mediterranean Sea, low salinity is strictly related to direct freshwater input and associated nutrients. As such salinity may be simply correlated to other environmental drivers, rather than be a driver itself.

Statistically significant correlations were the same when all holococcolithophores, paired holococcolithophores or the HOLP-index was considered at both locations - however fewer significant correlations were observed for paired holococcolithophores and the HOLP-index.

The trend for heterococcolithophore is less clear when comparing the two sites: an opposite trend to holococcolithophores - e.g. high nutrients and low temperatures - is observed in the Mediterranean Sea, but not in the Atlantic Ocean where many of the correlations were not significant and heterococcolithophore were negatively correlated to phosphate. This negative correlation to phosphate is potentially due to deeper sampling in the Atlantic Ocean combined with high phosphate concentrations in deep and light limited waters skewing correlations, which highlights the need to consider sampling and DCM depth when com-

paring environmental correlation between studies. It may furthermore be due to the presence of mixotrophic or heterotrophic coccolithophores at depth in the Atlantic Ocean, which are not found in the shallow coastal waters of the Mediterranean Sea.

### 3.4 Niche overlap and niche expansion

We conducted niche similarity and niche expansion calculations on both the Atlantic Ocean and Mediterranean data sets to quantify niche space in these regions. For niche overlap we considered the Jaccard overlap and Sørensen-Dice overlap metrics which range from 0 to 1, with 1 signifying complete overlap. For niche expansion we considered the relative amount each life cycle contributed to the total niche space. In the Atlantic Ocean the niche overlap of paired species was high for both the Jaccard overlap and Sørensen-Dice overlap metrics (0.84 and 0.91 respectively, Table 8). However, for individual species the overlap metrics were highly variable ranging from 0.11 - 0.74 and from 0.20 - 0.81 for the Jaccard overlap and Sørensen-Dice overlap metrics respectively. The niche expansion was higher for heterococcolithophores than holococcolithophores when all paired species were considered (see Table 8), but was again highly variable for individual species. The holococcolithophore phase of *C. mediterranea*, *S. bannockii*, *H. wallichii*, and *C. leptoporus* for instance all contributed more to the total niche space than their heterococcolithophore life cycle phase.

In the Mediterranean Sea niche overlap values were smaller, and niche expansion values were larger than in the Atlantic Ocean (Table 9). Niche expansion of heterococcolithophores was also higher than holococcolithophores when all paired species were considered, but like in the Atlantic Ocean species specific exceptions were observed. The holococcolithophore phase of *C. mediterranea*, *S. histrica*, *S. strigilis* and *C. leptoporus* all contributed more to the total niche space than their heterococcolithophore life cycle phase in this region. In the Mediterranean Sea the niche space of *S. molischii* is of particular note, as no overlap between the two life cycle phases was observed, and the two unique components were of similar size (0.51 and 0.49 for hetero- and holococcolithophores respectively).

Although quantitative interpretation of niche space is difficult since niche space will vary depending on the number of environmental axes included (Blonder et al., 2014), these results highlight that holococcolithophores contribute significantly to the niche space of coccolithophores, in some instances contributing more to total niche space than the heterococcolithophore phase. In this context *C. pelagicus* is particularly relevant as this species contributes significantly to the global carbonate flux (Ziveri et al. (2007); Rigual Hernández et al. (2019), and is one of the key calcifiers in the Arctic Ocean (Daniels et al., 2016).

These results additionally suggest that the niche expansion and difference in niche preference between the two life cycle phases is higher in the Mediterranean Sea than the Atlantic Ocean. It is however not clear if this is because the haplo-diplontic life cycle is better suited to more variable coastal environments as suggested by Godrijan et al. (2018) or due to higher temporal sampling resolution in the Mediterranean Sea data set compared to the Atlantic Ocean data set.

### 3.5 Seasonality of coccolithophores

Hetero- and holococcolithophore abundance highly varies with season at both the BATS station in the Atlantic Ocean and the long-term stations in the Mediterranean sea (Fig. 7). Both locations experience a peak of heterococcolithophores in the winter, followed by a peak of holococcolithophores at the end of spring, and in early summer. In the Atlantic Ocean, the heterococcolithophore

ithophore are present in high abundance for a longer period of time - overlapping with the spring peak in holococcolithophore  
310 abundance (Fig. 7a).

At both locations the peak of the holococcolithophore bloom occurs in the spring and summer when water temperatures  
rise and the day length is longest, while heterococcolithophore abundance is highest in the winter when temperature is lowest  
and day length shortest. The seasonality of peak hetero- and holococcolithophore abundance may furthermore correspond to  
seasonal changes in mixed layer depth (MLD), as both the Atlantic Ocean and Mediterranean Sea experience increased mixing  
315 in the winter and higher stratification in the summer.

No clear seasonal patterns were observed for fixed nitrogen or silicate concentrations at either location. Which suggest that  
although hetero- and holococcolithophores abundance is correlated to nutrient concentrations on spatial scales (see Sect. 3.3),  
on a seasonal scale other drivers such as temperature, light availability, and mixed layer depth predominate.

It is important to note that on a species level, individual species do not exclusively follow the seasonal hetero-holococcolithophore  
320 trends described above, as illustrated in detail by the original publications (Cerino et al., 2017; Godrijan et al., 2018). For in-  
stance for *Syracosphaera molischii* and *Syracosphaera pulchra* the holococcolith rather than heterococcolith phase is the dom-  
inant life cycle phase in these time series. Furthermore the holococcolithophore phases of *S. molischii*, *Syracosphaera histrica*,  
*Algirosphaera robusta* and *Acanthoica quattrosipina* are observed in the winter - a period when total holococcolithophore abun-  
dance is lowest. Finally on a individual level, succession does not immediately follow the previous life cycle phase with several  
325 months of absence observed between peak abundance for some species (Cerino et al., 2017; Godrijan et al., 2018).

This highlights that grouped hetero-holococcolithophore abundances represents a generalization that might not always rep-  
resent patterns observed for individual species. These differences from generally observed patterns could be due to variations  
in life strategy - such as mixotrophy, motility and grazing susceptibility - independent of life cycle phase. Suggesting that  
functional traits different from the life cycle phase may determine the niche space these species inhabit.

#### 330 4 Discussion

Our meta-analysis shows that holococcolithophores are important contributors to coccolithophore abundance and ecology,  
contributing  $\approx 7.3\%$  to total coccolithophore abundance. Our analysis furthermore shows that haploid cells play an important  
role in coccolithophore species that calcify in their haploid phase, accounting on average for  $\approx 18.3\%$  of their total abundance.

Although holococcolithophore contribution to calcium carbonate production is likely small due to their lower cellular  $\text{CaCO}_3$   
335 content - which is an order of magnitude lower than heterococcolithophores (Daniels et al., 2016; Fiorini et al., 2011a, b) - their  
role in the carbonate cycle in present, past and future oceans is not to be underestimated. A shift towards a higher proportion  
of holococcolithophore cells, would result in lower global calcium carbonate production which would subsequently result in  
lower  $\text{CO}_2$  outgassing on short time scales. Furthermore the ballasting effect of coccolithophores would be reduced if a shift  
towards more lightly calcified haploid cells occurred (Hoffmann et al., 2015).

340 In terms of the ecological niche space - which is the environmental range a species inhabits - hetero- and holococcol-  
ithophores observations in our meta-analysis broadly conform to the Margalef Niche Space Model, proposed by Margalef

(1978), which posits that the distribution of phytoplankton functional groups relate broadly to turbulence, light and nutrients. Within this framework, we find that hetero- and holococcolithophores occupy an intermediate functional group located between diatoms and dinoflagellates (see Fig. 8) as proposed by Houdan et al. (2006) and Frada et al. (2018). Diploid heterococcolithophores thus favour high nutrient, and more turbulent waters, whereas haploid holococcolithophores favour low nutrient, and more stratified waters.

Although the Margalef niche space model certainly presents a simplification that is prone to exceptions both for diatoms (see Kemp and Villareal (2018)) as well as coccolithophores (The generalist *E. huxleyi* and deep water species such as *F. profunda* are clear examples), the model broadly holds in our meta-analysis.

This ecological-environmental distinction of hetero- and holococcolithophores is observed in coccolithophore species distribution in our analysis in terms of geographical succession, depth distribution and seasonal trends. In the Southern Ocean and Atlantic Ocean a geographical shift from holococcolithophores to heterococcolithophores is observed as latitude and turbulence and nutrients increases. While in the Atlantic Ocean as well as the global data set a vertical shift is observed with holococcolithophores absent or at low abundance in deep nutrient rich waters. Finally, in the Mediterranean Sea, a seasonal shift is observed as heterococcolithophores are most abundant in well mixed nutrient rich winter months and holococcolithophore are most abundant in nutrient poor stratified summer months.

However, some exceptions occur. For instance in the AMT data set, although heterococcolithophores are more evenly distributed with depth, maximum abundance of heterococcolithophores is in surface waters, and subsequently heterococcolithophores are negatively correlated to nutrients. Nonetheless the relation to turbulence holds: heterococcolithophore abundance is highest in well mixed high latitude waters and holococcolithophore abundance is highest in stratified sub-tropical regions. Finally, many species specific exceptions occur. We highlight examples on a seasonal scale in our Mediterranean data set discussion (see Sect. 3.6), but exceptions were also noted along the AMT (see discussion in Poulton et al. (2017), and in other Mediterranean studies (Šupraha et al., 2016; ?; Skejić et al., 2018). Which means that caution should be used when considering the niche space model for individual species.

#### 4.1 Niche overlap and expansion

Our study showed that the niche volume of coccolithophores is larger when holococcolithophores are included in coccolithophore niche space. This tells us two things: first, studies focused solely on heterococcolithophore are underestimating coccolithophore habitat and thus inaccurately represent the coccolithophore functional group in modelling and physiological studies, which means that we might be underestimating their ability to compete with other phytoplankton, as well as the range of environmental conditions they can tolerate. Secondly, we are underestimating the importance of coccolithophore primary productivity and carbonate production by not including accurate assessments of their abundance or activity.

This might be of particular relevance for *E. huxleyi*, the diploid phase of which has been of particular research focus due to high abundances (approx 59.2% in our compilation). Although our meta-analysis does not include haploid abundance data of this species, we suspect, following upon our findings on the haploid/diploid paired species, that the haploid phase of *E. huxleyi* is also ecologically relevant. Previous studies suggest that the haploid life cycle phase of *E. huxleyi* can increase its

niche space due to streamlined metabolism (Rokitta et al., 2011), and variations in response to bacterial (Mayers et al., 2016; Bramucci et al., 2018), and viral pressures (Frada et al., 2008). Although it should be noted that in some instance, morphology rather than ploidy level seems to be the primary driver for observed differences in *E. huxleyi* (Frada et al., 2017). Overall, observations in the haploid stage of *E. huxleyi* are extremely limited due to difficulty of identifying the haploid phase with  
380 regular light microscopy, highlighting the need for developing new techniques to account for this potentially important life cycle stage. Further development of the COD-FISH method as described by Frada et al. (2012) in particular would be relevant in this context.

## 4.2 Concluding remarks

Our compilation provides insight into the distribution of hetero- and holococcolithophores, but also highlights many gaps in  
385 the data distribution and our knowledge on coccolithophore ecology. There is for instance a lack of SEM observations in the Pacific Ocean (2 studies in this compilation), and there are a limited number of time series available, which are particularly valuable due to the seasonal nature of these organisms. Patchiness of data combined with the patchiness of coccolithophore blooms is a challenge in fully assessing marine ecosystem functioning, and in providing global abundance estimations. Beside limitations of in situ measurements, size, POC and PIC measurements of paired hetero- and holococcolithophore species are  
390 sparse, in particularly for holococcolithophores.

Such measurements are needed for global organic carbon and carbonate production estimates, which are critical for biogeochemical estimates, including model studies. Models which could then be used to contextualize in situ observations in biogeochemical context, and which could test response to environmental pressures presented by anthropogenic CO<sub>2</sub> emissions. Modelling approaches could furthermore be used to investigate drivers of distribution trends difficult to acquire with in  
395 situ measurements such as the role of competition with other phytoplankton and the influence of top down control on distribution trends, both of which have shown to be important drivers of coccolithophore distribution in previous studies (Monteiro et al., 2016; Nissen et al., 2018).

A pertinent environmental driver not covered in our meta-analysis due to limited data, is the influence of carbonate chemistry within the haploid-diploid niche space. As the haploid and diploid phases of coccolithophores vary in their calcification status,  
400 they may thus show different responses to carbonate chemistry. A study by Triantaphyllou et al. (2018) for instance found that holococcolithophores increased abundance in low pH waters. If this holds true on a global level, and holococcolithophores inhabit lower pH waters in terms of their niche space, this would have important implication in the context of ocean acidification. In particular because meta-analysis (Ridgwell et al., 2009; Krumhardt et al., 2017) and modelling (Ridgwell et al., 2007; Krumhardt et al., 2019) suggest a shift towards lower global calcification rates in response to ocean acidification and warming.  
405 It should however be noted that the response of heterococcolithophores to ocean acidification is both strain and species dependent (Langer et al., 2006, 2009; Meyer and Riebesell, 2015), and global calcification rates might be more impacted by shifts in species compositions rather than individual response (Ridgwell et al., 2009).

Finally, additional experiments on the numerical response of hetero- and holococcolithophores to various environmental drivers such as those performed on *E. huxleyi* would allow a better understanding of individual environmental pressures, and

410 will furthermore be highly valuable for future modelling approaches. In this context a better understanding of the triggers of phase transition would additionally be highly desirable, as the lack of haploid-diploid pairs of the same strain limits genomic approaches.

## 5 Conclusions

Our analysis shows that holococcolithophores constitute a large proportion of total coccolithophore abundance ( $\approx 18\%$  for 415 paired species). Our study furthermore shows that hetero- and holococcolithophores have contrasting environmental preference, and that therefore the haplo-diplontic life cycle expands the niche space coccolithophores can inhabit by  $\approx 17\%$ . Although our findings are limited to holococcolith forming species, lab studies suggest similar patterns are likely to be observed for other coccolithophore species such as *E. huxleyi*, and raises the question how much the haploid phase of this species contributes to global coccolithophore abundance.

420 These results highlight the need to include haploid cells into coccolithophore studies, both in the context of environmental studies, modelling approaches, and physiological studies. We limit our understanding of these organisms by just focusing on one life cycle phase, particularly in the context of coccolithophore response to climate change, as increased stratification in a warming climate may favour the haploid life cycle of coccolithophores.

*Data availability.* The data from the compilation will be available on PANGAEA

425 *Author contributions.* JV, FM, GW and CB conceptualized the manuscript. AP, JG, and FC provided data for analysis. JV curated the data, performed the formal analysis and visualized the results. JV, FM, CB, AP, JG, FC, GL, and EM interpreted the results. JV and FM prepared the manuscript with contributions from all co-authors.

*Competing interests.* The authors declare that they have no conflict of interest

*Acknowledgements.* This research was supported by a NERC GW4+ DTP and the Natural Environment Research Council (NERC) [NE/L002434/1] 430 studentship to JV. It was also supported by the Natural Environment Research Council grant (NE/N011708/1) to CB, GW, FM, and FM; the European Research Council grant ERC-ADG-670390 to CB; the NERC consortium grant (NER/O/S/2001/00680) and a NERC Fellowship (NE/F015054/1) to AP; and the Croatian Ministry of Science, Education and Sports (No. 098-0982705-2731) and European Community Research Infrastructure Action under the FP7 "Capacities" Program (SYNTHESSYS, Project GB-TAF-132) to JG. The Atlantic Meridional Transect is funded by the UK Natural Environment Research Council through its National Capability Long-term Single Centre Science Pro- 435 gramme, Climate Linked Atlantic Sector Science (grant number NE/R015953/1). This study contributes to the international IMBeR project

and is contribution number 349 of the AMT programme. The C1-LTER station is part of the national and international Long Term Ecological Research network (LTER-Italy, LTER-Europe, ILTER). Data for the C1-LTER station were obtained in the framework of the EU FP7 MedSeA (Mediterranean Sea Acidification in a Changing Climate) project. Environmental and nutrient data were made available through the OGS Italian National Oceanographic Data Center (NODC). This is a scientific contribution of Project MIUR - Dipartimenti di Eccellenza 440 2018-2022 to the DISAT of Milano-Bicocca. We would like to thank for the statistical clinics provided by the Institute for Statistical Science at the University of Bristol. Finally we would like to thank everyone who as contributed data to the compilation.

### A. Haplontic life cycle (Dinoflagellates)

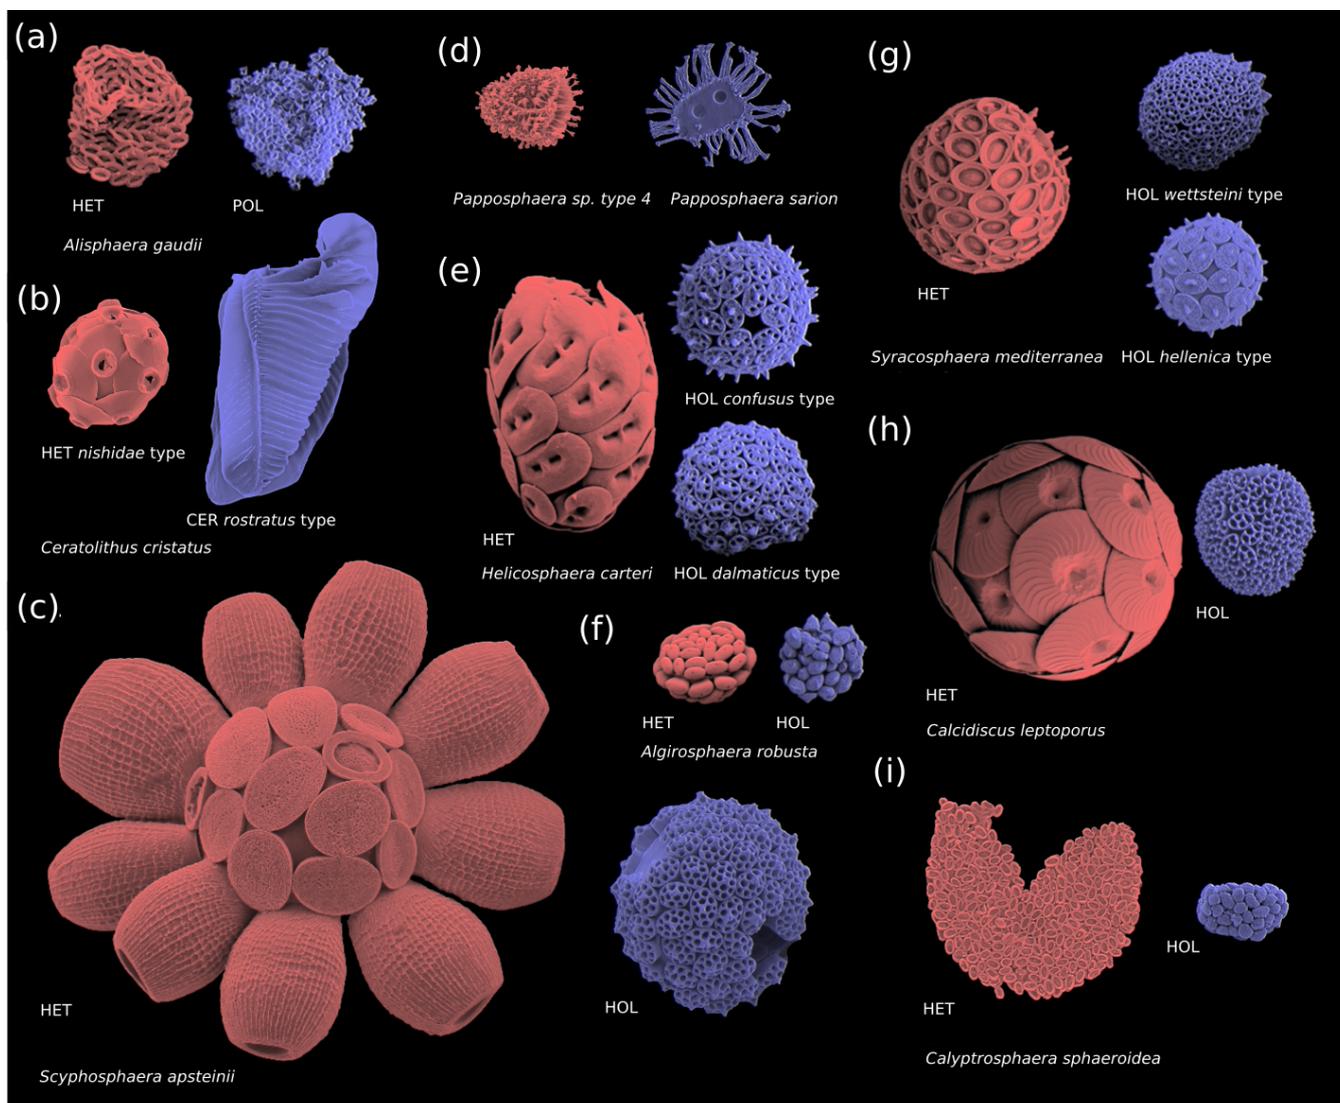

### B. Diplontic life cycle (Diatoms)

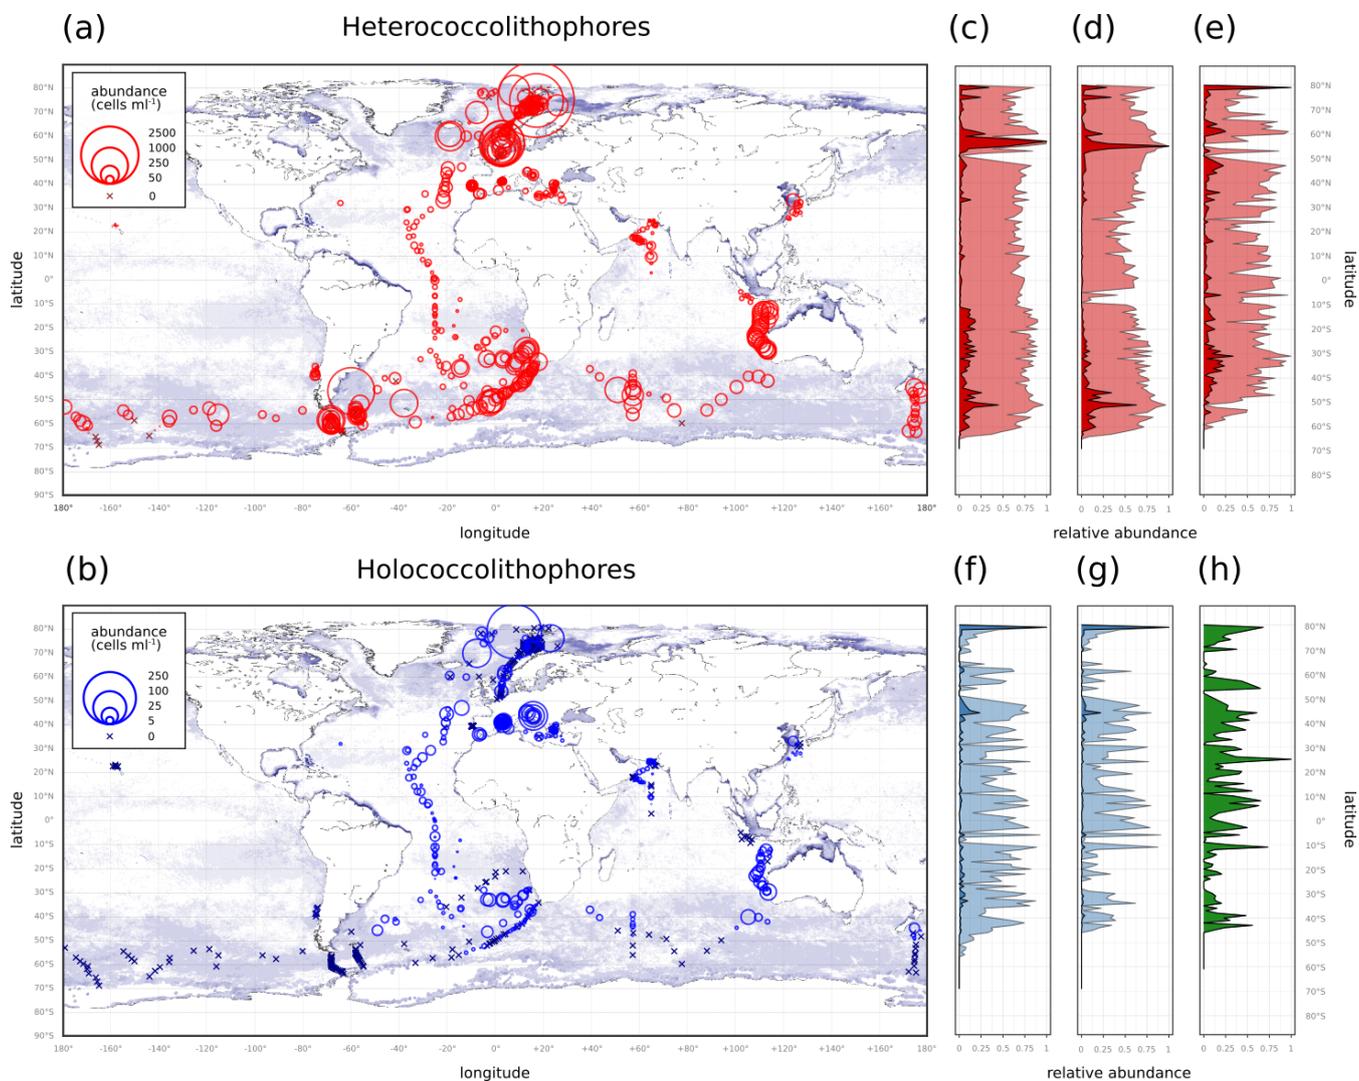

### C. Haplo-diplontic life cycle (Coccolithophores)

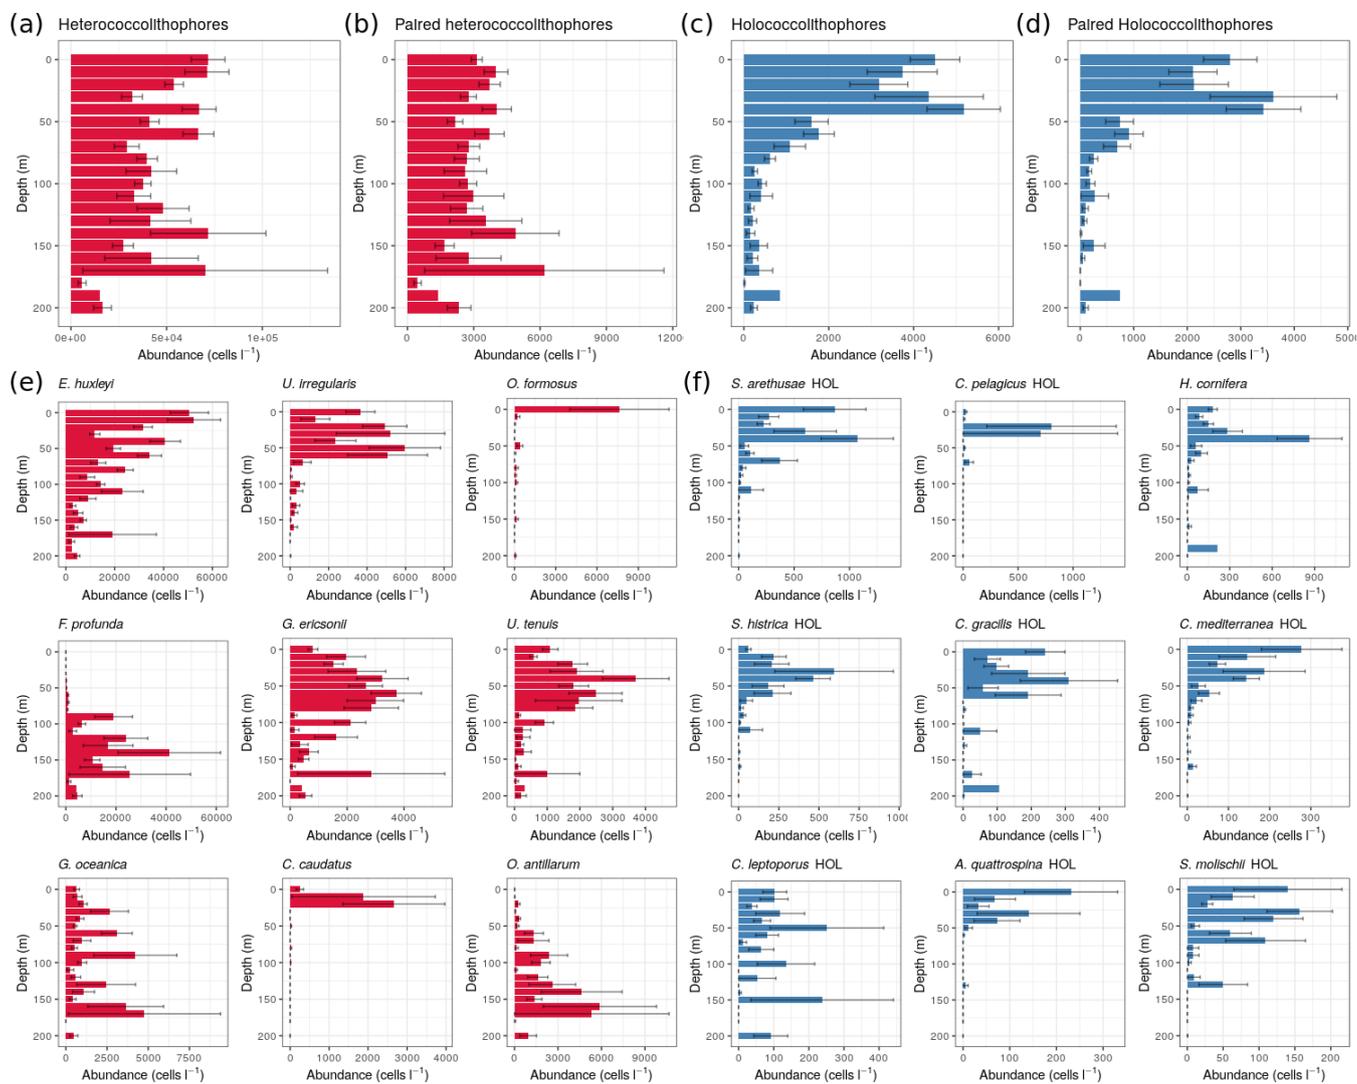

**Figure 1.** Life cycle strategies of phytoplankton. (a) Dinoflagellates tend to utilize a haplontic life cycle; (b) Diatoms tend to utilize a diplontic life cycle; (c) coccolithophores tend to utilize a haplo-diplontic life cycle. Note that not all coccolithophores calcify in their haploid phase.

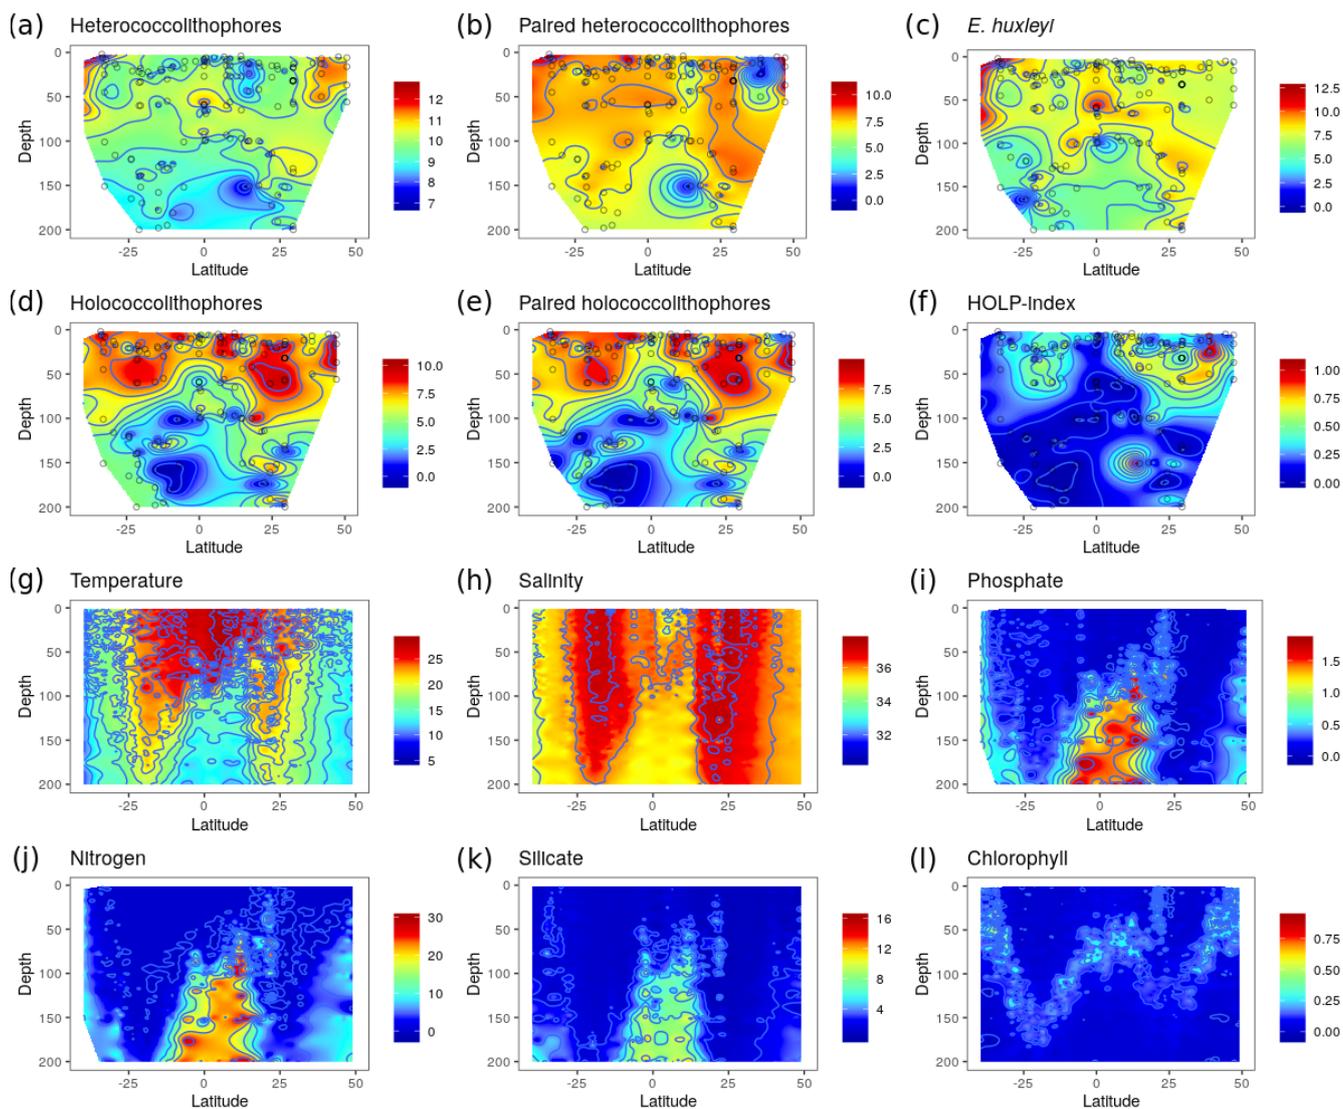

**Figure 2.** Coccosphere diversity of common coccolithophores. Haploid cells are colored in blue and diploid cells in red. **(a)** Polycrater haploid morphology; **(b)** Ceratolith haploid morphology; **(c-i)**. Holococcolith haploid morphology. Note that in some instances multiple haploid phases are associated with one diploid phase (e.g. *S. mediterranea* and *H. carteri*), which may be due to cryptic speciation (Geisen et al., 2002). Furthermore, some species (e.g. *E. huxleyi*) do not calcify in their haploid phase and are thus not pictured. Images reproduced with permission from Young et al. **(b-d, i)**, and Šupraha et al. (2016) **(a, e-h)**. Images **(b-d, i (HOL))** by Jeremy Young, **(i (HET))** by Marie-Helene Kawachi, **(a, e-h)** by Luka Šupraha.

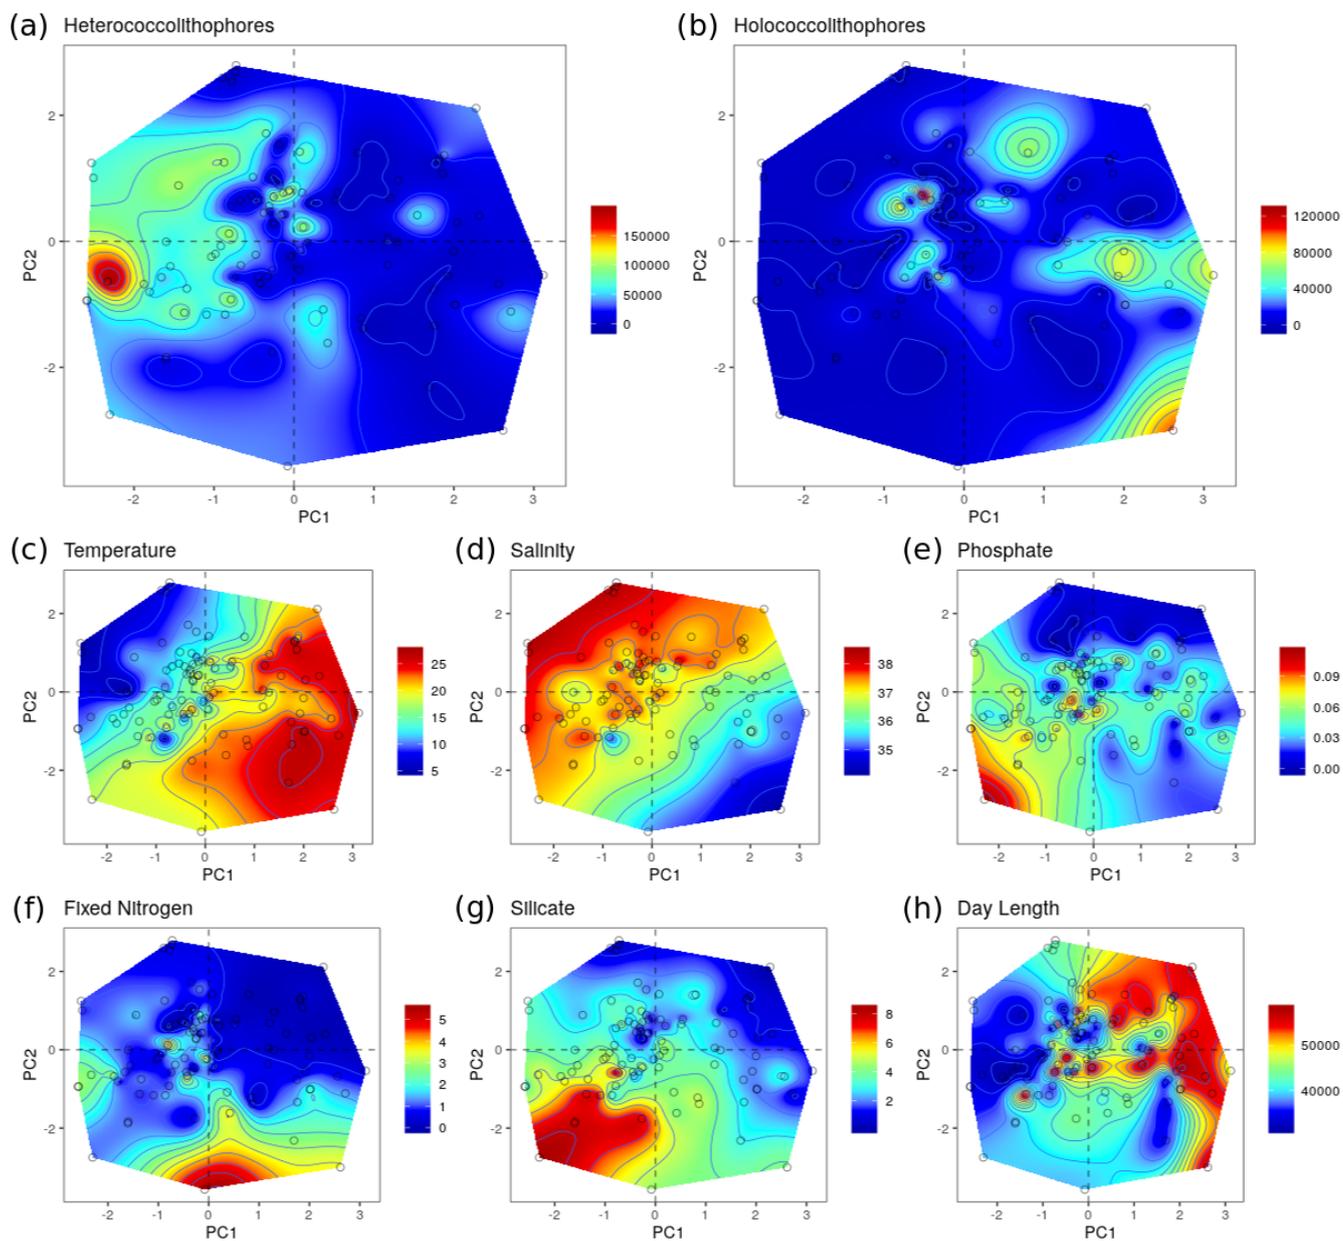

**Figure 3.** (a-b) Global coccolithophore distribution; (c-h) latitudinal coccolithophore distribution. (a) Heterococcolithophores; (b) Holococcolithophores; (c) Heterococcolithophores; (d) *E. huxleyi*; (e) Paired heterococcolithophores; (f) Holococcolithophores; (g) Paired holococcolithophores; (h) HOLP-index. For the latitudinal plots, the light shading is log transformed distribution.

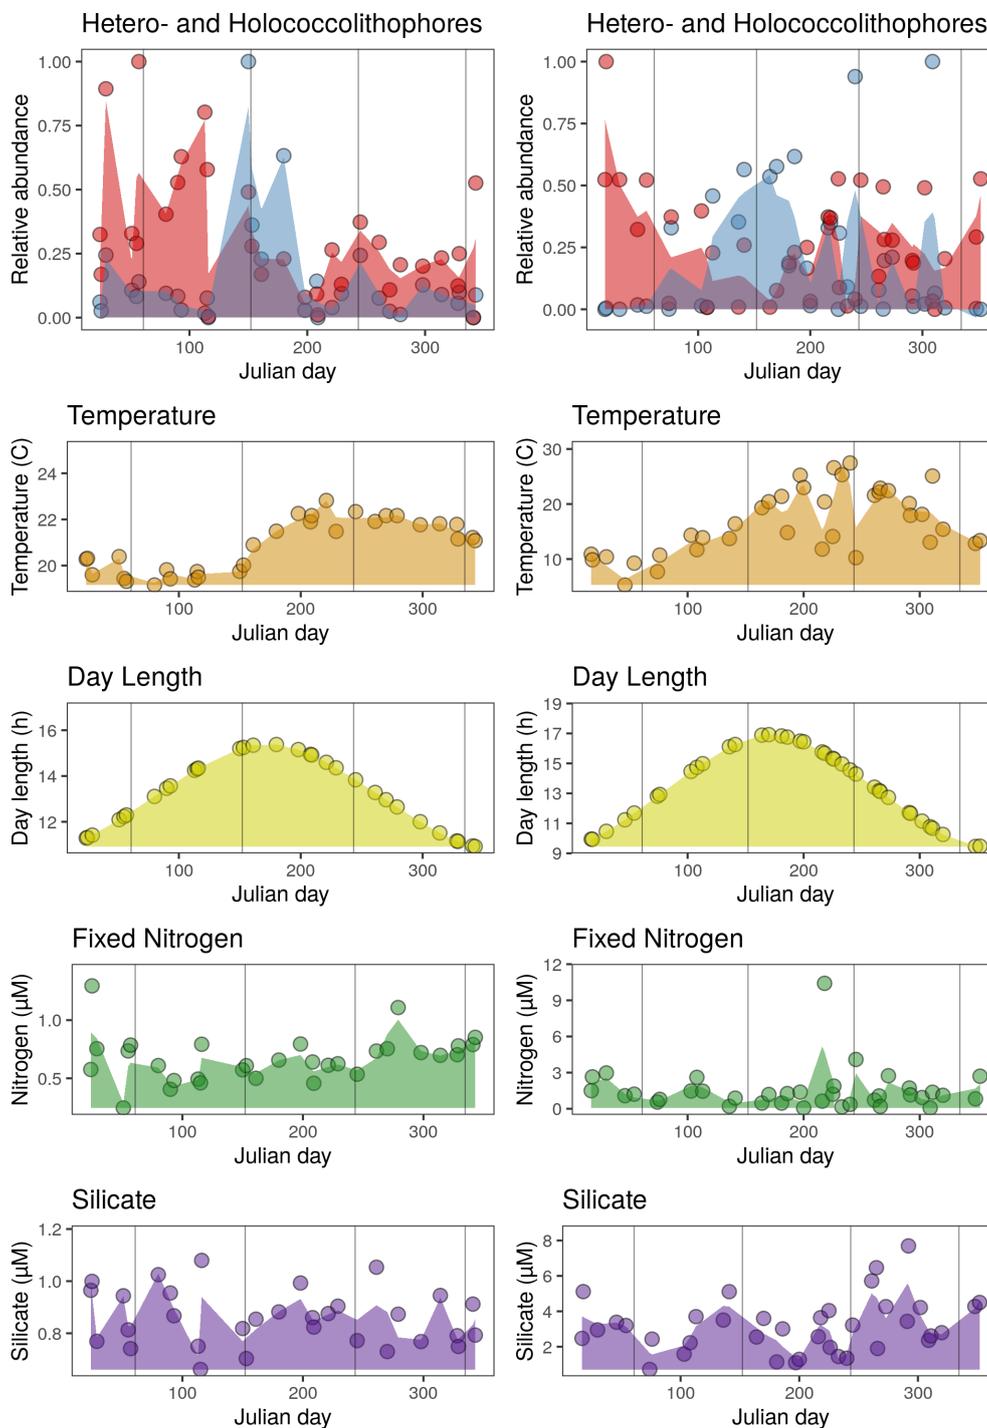

**Figure 4.** Global depth distribution of hetero- and holococcolithophores. (a-d) total paired and unpaired hetero- and holococcolithophore abundance; (e-f) individual species abundances. Heterococcolithophores are plotted in blue, and holococcolithophores are plotted in red. Only the most abundant coccolithophore species are plotted individually. Error bars are standard error.

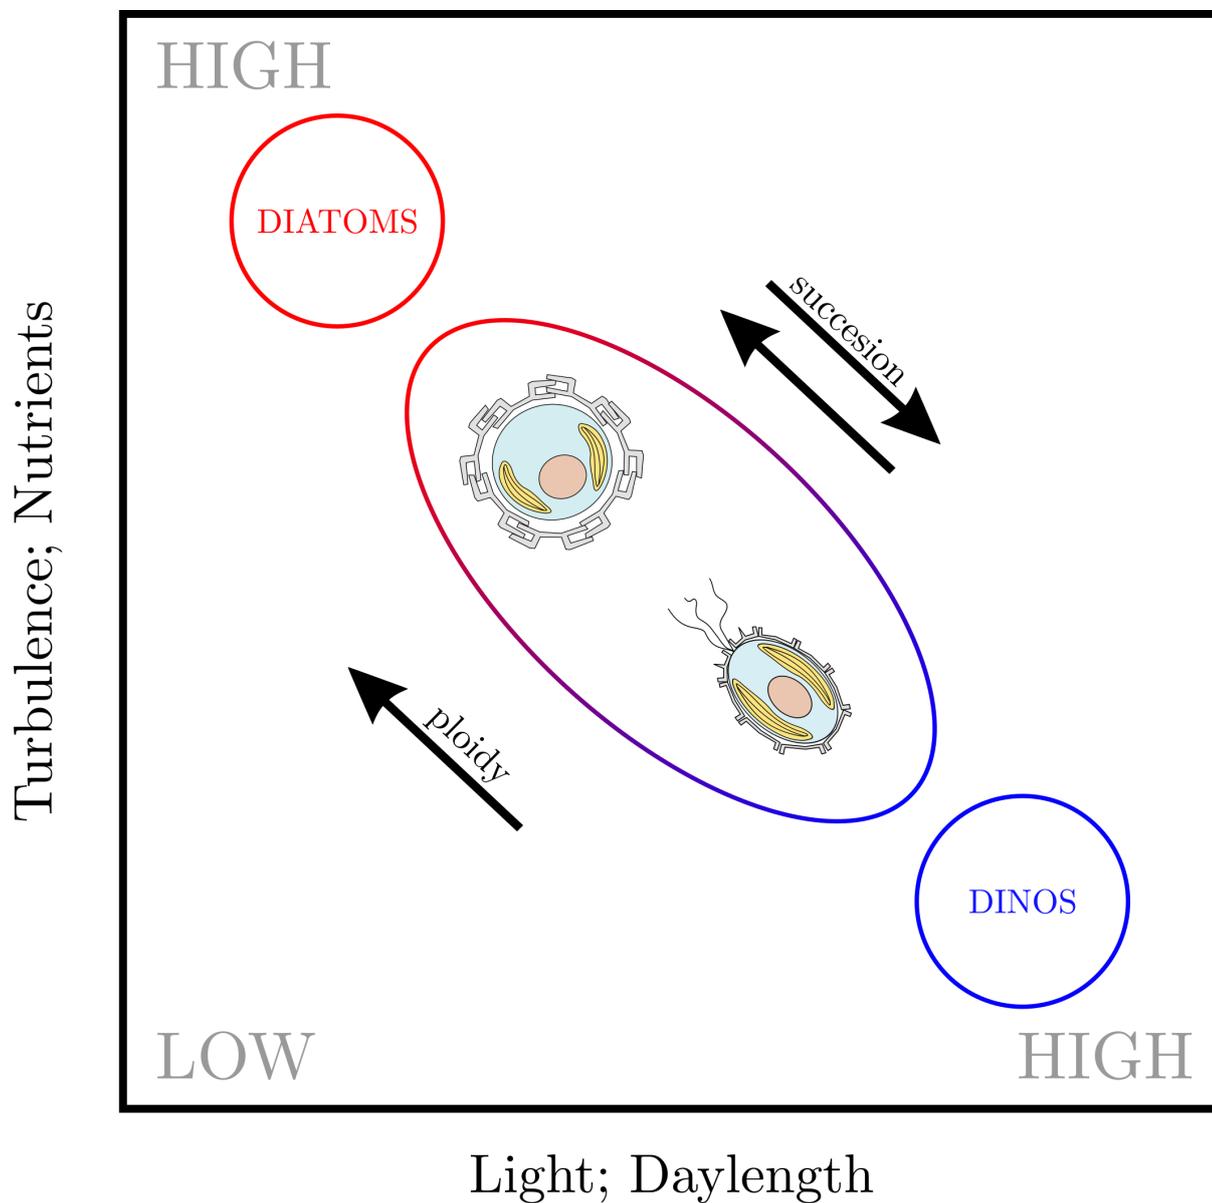

**Figure 5.** Depth distribution along AMT. (a) Heterococcolithophore abundance; (b) Paired heterococcolithophore abundance; (c) *E. huxleyi* abundance; (d) Holococcolithophore abundance; (e) Paired holococcolithophore abundance; (f) HOLF-index; (g) Temperature ( $^{\circ}$  C); (h) Salinity (ppt); (i) Phosphate ( $\mu$ M); (j) Silicate ( $\mu$ M); (l) Chlorophyll. Species abundances are plotted on log scale.

**Figure 6.** Principal Component analysis (PCA) of the RV-001 and LTER1 stations in the Mediterranean Sea. Abundance and environmental values were projected on the PCA *post hoc*, and then interpolated. (a) Heterococcolithophore abundance; (b) Holococcolithophore abundance; (c) Salinity; (d) Temperature; (e) Depth; (f) Phosphate; (g) Fixed nitrogen; (h) Silicate. Data was acquired from Cerino et al. (2017) and Godrijan et al. (2018).

**Figure 7.** Seasonality of hetero- and holococcolithophores at the BATS station in Bermuda (left column) and the RV-001 and LTER-1 stations in the Mediterranean Sea (right column). For the hetero- and holococcolithophore plots, heterococcolithophores are plotted in red and holococcolithophores are plotted in blue.

**Figure 8.** A. Modified version of Margalef's niche space model (Margalef, 1978) as proposed by Houdan et al. (2006) and Frada et al. (2018). Note that we have added day length, which was proposed by Balch (2004) as a third axis of the Margalef niche space model.

**Table 1.** Overview of Metadata.

Values in parentheses are standard deviations.

**Table 4.** Global HOLP-index

Location	mean (%)	n
Global	18.33% ( $\pm 28.19\%$ )	1836
Arabian Sea	18% ( $\pm 34.83\%$ )	102
Arctic Circle	15.66% ( $\pm 31.89\%$ )	108
Central Atlantic	16% ( $\pm 23.94\%$ )	117
East China Sea	17.06% ( $\pm 26.61\%$ )	40
East Indian Ocean	0%	85
Hawaii	0%	9
Mediterranean Sea	27.69% ( $\pm 30.08\%$ )	709
North Atlantic	16.43% ( $\pm 25.41\%$ )	174
South Pacific Ocean	36.19% ( $\pm 37.43\%$ )	30
Southern Ocean	7.05% ( $\pm 23.73\%$ )	141

Values in parentheses are standard deviations.

**Table 5.** PCA loadings of Mediterranean Sea data set

Variable	PC1	PC2
Temperature	1.57	-0.75
Salinity	-1.25	1.23
Fixed Nitrogen	-0.42	-1.04
Silicate	-0.98	-1.27
Phosphate	-0.81	-0.89
DayLength	1.17	0.27

The first two axis of the PCA captured 53.94% of variance. Data from Cerino et al. (2017) and Godrijan et al. (2018)

**Table 6.** Spearman correlations for AMT data set

Phase	Temp	Sal	PO4	NOx	Depth	Si
